

# Assessing the Vulnerability of the Fiber Infrastructure to Disasters

Sebastian Neumayer, *Member, IEEE*, Gil Zussman, *Senior Member, IEEE*, Reuven Cohen, and Eytan Modiano, *Senior Member, IEEE*

**Abstract**—Communication networks are vulnerable to natural disasters, such as earthquakes or floods, as well as to physical attacks, such as an electromagnetic pulse (EMP) attack. Such real-world events happen in specific geographical locations and disrupt specific parts of the network. Therefore, the geographical layout of the network determines the impact of such events on the network's connectivity. In this paper, we focus on assessing the vulnerability of (geographical) networks to such disasters. In particular, we aim to identify the most vulnerable parts of the network. That is, the locations of disasters that would have the maximum disruptive effect on the network in terms of capacity and connectivity. We consider graph models in which nodes and links are geographically located on a plane. First, we consider a simplistic bipartite graph model and present a polynomial-time algorithm for finding a worst-case vertical line segment cut. We then generalize the network model to graphs with nodes at arbitrary locations. We model the disaster event as a line segment or a disk and develop polynomial-time algorithms that find a worst-case line segment cut and a worst-case circular cut. Finally, we obtain numerical results for a specific backbone network, thereby demonstrating the applicability of our algorithms to real-world networks. Our novel approach provides a promising new direction for network design to avert geographical disasters or attacks.

**Index Terms**—Electromagnetic pulse (EMP), fiber-optic, geographically correlated failures, network survivability.

## I. INTRODUCTION

THE GLOBAL communications infrastructure is primarily based on fiber-optic networks and, as such, has physical vulnerabilities. Fiber links and backbone nodes can be destroyed by anything from electromagnetic pulse (EMP) attacks [14],

Manuscript received July 08, 2010; revised January 19, 2011; accepted March 01, 2011; approved by IEEE/ACM TRANSACTIONS ON NETWORKING Editor S. Subramaniam. [15], [31] to dragging anchors [8], [36]. Such real-world disasters happen in specific geographic locations, and therefore, the geographical layout of the network affects their impact. For example, an EMP is an intense energy field that can instantly overload or disrupt numerous electrical circuits at a large distance, thereby affecting electronic components in a large geographic area [37]. Hence, such an attack over a U.S. city that is a telecommunications hub would have a disastrous impact on U.S. telecommunications capabilities. Our approach is to gain insight into robust network design by developing the necessary theory to find the most geographically vulnerable areas of a network. This can provide important input to the development of network design tools and can support the efforts to mitigate the effects of regional disasters.

There are several works on the topology of the Internet as a random graph [4] and on the effect of link failures in these graphs [12], [23] (for more details, see Section II). However, most of these works are motivated by failures of routers due to logical attacks (e.g., viruses and worms) and thereby focus on the logical Internet topology. There have also been some attempts to model the Internet using geographical notions [21], [39]. Yet, these works do not consider the effect of failures that are geographically correlated. Finally, [29] studied the network inhibition problem in which a set of links has to be removed from a graph such that the effect on the graph will be maximized. Yet, to the best of our knowledge, the network inhibition problem was not studied under the assumption of geographically correlated failures.

Since disasters affect a specific geographical area, they will result in failures of neighboring network components. Therefore, one has to consider the effect of disasters on the physical layer rather than on the network layer (i.e., the effect on the fibers rather than on the logical links). It should be noted that fibers are subject to regional failures resulting from events such as earthquakes, floods, and even an EMP attack, as these may lead to failure of the electrical circuits (e.g., amplifiers) that are needed to operate the fiber plant [37].

Our long-term goal is to understand the effect of a regional failure on the bandwidth, connectivity, and reliability of the Internet, and to expose the design tradeoffs related to network survivability under a disaster with regional implications. Such tradeoffs may imply that in certain cases there may be a need to redesign parts of the network, while in other cases there is a need to protect electronic components in critical areas (e.g., protecting against EMP attacks by shielding [15], [31]). In this paper, we are interested in the location of geographical disasters that have the maximum effect on the network in terms of capacity and connectivity. That is, we want to identify the

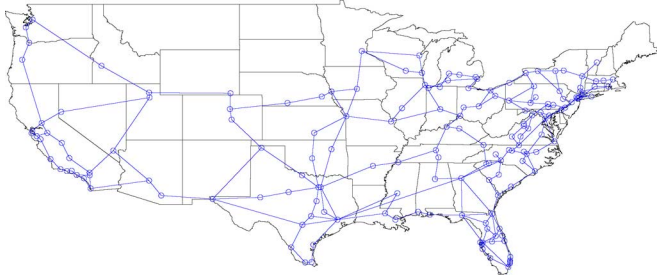

Fig. 1. Fiber backbone operated by a major U.S. network provider [22].

worst-case location for a disaster or an attack as well as its effect on the network.

The global fiber plant has a complicated structure. For example, Fig. 1 presents the fiber backbone operated by a major network provider in the U.S. (point-to-point fibers are represented by straight lines). We consider two graph models that serve as an abstraction of the continental/undersea fiber plant. In these models, nodes, links, and cuts are geographically located on a plane. Nodes are represented as points, and links are represented as line segments between these points. We first study a bipartite graph model (in the topological and geographical sense). That model is analogous to the east and west coasts of the U.S., where nodes on the left and right sides of the graph represent west and east coast cities (respectively) and the cities within the continent are ignored. Similarly, it can represent transatlantic or transpacific cables. Since vertical line segment cuts are simpler to analyze, we focus initially on such cuts and provide some motivating examples.

However, the bipartite model does not consider the impact on nodes located within the continent, nor does it consider the impact of a disaster that is not simply a vertical cut. Therefore, we later relax the *bipartite* graph and *vertical* cut assumptions by considering a general model where nodes can be arbitrarily located on the plane. Under this model, we consider two problems. In the first one, disasters are modeled as line segment cuts (not necessarily vertical) in the network graph. In the second one, disasters are modeled as circular areas in which the links and nodes are affected. These general problems can be used to study the impact of disasters such as EMP attacks (circular disks) and tornadoes (line segments) more realistically.

We assume that a regional disaster affects the electronic components of the network within a certain region. Hence, the fibers that pass through that region are effectively cut due to such a disaster. There are various performance measures for the effect of a cut. We consider the following: 1) the expected capacity of the removed links; 2) the fraction of pairs of nodes that remain connected; 3) the maximum possible flow between a given source–destination pair; and 4) the average maximum flow between pairs of nodes. We show that although there is an infinite number of cut locations, only a polynomial number of candidate cuts has to be considered in order to identify a worst-case cut for these performance measures in any of the problems above. Thus, we are able to show that the location of a worst-case cut can be found by polynomial-time algorithms. It should be noted that any other quantity that can be calculated in polynomial time may be used as a performance measure. Hence, measures such

as concurrent maximum flow and other measures that are derived from multicommodity flow problems may also be used.

Finally, we present numerical results and demonstrate the use of these algorithms. We identify the locations of the worst-case line segment and circular cuts in the network presented in Fig. 1.<sup>1</sup> In particular, we illustrate the locations of cuts that optimize the different performance measures described.

The main contributions of this paper are the formulation of a new problem (termed as the *geographical network inhibition* problem), the design of algorithms for its solution, and the demonstration of the obtained numerical solutions on a U.S. infrastructure. To the best of our knowledge, we are the first to attempt to study this problem.

This paper is organized as follows. We briefly discuss related work in Section II. In Section III, we introduce the network models and formulate the geographical network inhibition problems. In Section IV, we consider a simple case of the bipartite model and provide numerical examples that provide insight into the location of a worst-case cut. In Section V, we develop a polynomial-time algorithm for finding the worst-case cuts in the bipartite model. In Sections VI and VII, we study the general model with line segment and circular cuts. In Section VIII, we present numerical results. We conclude and discuss future research directions in Section IX.

## II. RELATED WORK

The issue of network survivability and resilience has been extensively studied in the past (e.g., [6], [18], [24], [41], and references therein). However, most of the previous work in this area and in particular in the area of physical topology and fiber networks (e.g., [25] and [26]) focused on a *small number of fiber failures* or on the concept of *Shared Risk Link Group* (SRLG) [20]. On the contrary, in this paper we focus on events that cause a large number of failures in a specific geographical region (e.g., [8], [15], [31], and [36]). To the best of our knowledge, *geographically correlated failures* have been considered only in a few papers and under very specific assumptions [2], [19], [38].

The theoretical problem most closely related to the problem we consider is known as the *network inhibition problem* [29]. Under that problem, each edge in the network has a destruction cost, and a fixed budget is given to attack the network. A feasible attack removes a subset of the edges, whose total destruction cost is no greater than the budget. The objective is to find an attack that minimizes the value of a maximum flow in the graph after the attack. A few variants of this problem were studied in the past (e.g., [9], [11], and [30]). However, as mentioned, the removal of (geographically) neighboring links has been rarely considered [7], [33]. One of the first and perhaps the closest to this concept is the problem studied in [34].

When the logical (i.e., IP) topology is considered, widespread failures have been extensively studied [12], [13], [17], [23]. Most of these works consider the topology of the Internet as a random graph [4] and use percolation theory to study the effects of random link and node failures on these graphs. The focus on the logical topology rather than on the physical topology is

<sup>1</sup>We present results only for one major operator. The same methodologies can be used in order to obtain results for all other major operators.

Fig. 2. Bipartite network and an example of a cut.

motivated by failures of routers due to attacks by viruses and worms. Based on various measurements (e.g., [16]), it has been recently shown that the topology of the Internet is influenced by geographical concepts [3], [21], [39]. These observations motivated the modeling of the Internet as a scale-free geographical graph [35], [40]. Although these models may prove useful in generating *logical* network topologies, we decided to present numerical results based on *real physical* topologies (i.e., the topology presented in Fig. 1).

### III. MODEL AND PROBLEM FORMULATION

In this section, we present three geographical network inhibition problems. The first problem assumes that the network is bipartite in the topological and geographic sense and that the cuts are vertical line segments. We then present two problems where network links can be in almost arbitrary locations on the plane. In one of the problems, the disasters correspond to line segment cuts in any direction. In the other, the cuts are modeled by arbitrarily placed circular disks on the plane.

#### A. Bipartite Model With Vertical Line Segment Cuts

We now define the *geometric* bipartite graph. It has a width of 1 and height (south-to-north) of  $h_G$ . The height of a left (west) node  $i$  is denoted by  $l_i$ . Similarly, the height of a right (east) node  $j$  is denoted by  $r_j$ . Nodes cannot overlap and must have nonnegative height; that is,  $r_i \neq r_j \geq 0 \forall i, j$  and  $l_i \neq l_j \geq 0 \forall i, j$ . Denote the total number of nodes on the left and right side by  $N$ . We denote a link from node  $i$  to node  $j$  as  $(i, j)$  and let  $(i, j)$  be represented by a line segment from  $[0, l_i]$  to  $[1, r_j]$ . We define  $p_{ij}$  as the probability that link  $(i, j)$  exists, and  $c_{ij}$  as the capacity of link  $(i, j)$ , where  $c_{ij} \in [0, \infty)$ . To avoid considering the trivial case in which there are no links with positive capacity, we assume that there exist some  $i$  and  $j$  for which  $c_{ij}p_{ij} > 0$ . We assume that the disaster results in a vertical line segment cut of height  $h$  whose lowest point is at point  $[x, y]$ . We denote this cut by  $\text{cut}_h(x, y)$ . Such a cut removes all links that intersect it. For clarity, in this paper we refer to the start and the end of a link as nodes and the start and the end of a cut as endpoints. Fig. 2 demonstrates a specific construction of the model and an example of a cut.

There are many ways to define the effect of a cut on the loss of communication capability in a network. We define the performance measures and the worst-case cut as follows.

*Definition 1 (Performance Measures):* The performance measures of a cut are (the last three are defined as the values after the removal of the intersected links):

- TEC: the total expected capacity of the intersected links;

- ATTR: the fraction of pairs of nodes that remain connected (this is similar to the average two-terminal reliability of the network<sup>2</sup>);
- MFST: the maximum flow between a given pair of nodes  $s$  and  $t$ ;
- AMF: the average value of maximum flow between all pairs of nodes.

*Definition 2 (Worst-Case Cut):* Under a specific performance measure, a *worst-case cut*, denoted by  $\text{cut}_h(x^*, y^*)$ , is a cut that maximizes/minimizes the value of the performance measure.<sup>3</sup>

We now demonstrate the formulation of the following optimization problem using the TEC performance measure.

1) *Bipartite Geographical Network Inhibition (BGNI) Problem:* Given a bipartite graph, cut height, link probabilities, and capacities, find a worst-case vertical line segment cut under performance measure TEC.

We define the following  $(0, 1)$  variables:

$$z_{ij}(x, y) = \begin{cases} 1, & \text{if } (i, j) \text{ is removed by } \text{cut}_h(x, y) \\ 0, & \text{otherwise.} \end{cases}$$

A solution to the following BGNI optimization problem is an endpoint of a worst-case cut:

$$\begin{aligned} \max \quad & \sum_{(i,j)} p_{ij}c_{ij}z_{ij}(x, y) \\ \text{such that} \quad & 0 \leq x \leq 1 \\ & -h \leq y \leq h_G. \end{aligned} \quad (1)$$

The above optimization problem can be formulated as a mixed integer linear program (MILP) as follows. Define the following  $(0, 1)$  variables:

$$\begin{aligned} u_{ij} &= \begin{cases} 1, & \text{if } (i, j) \text{ crosses the cut location } (x) \text{ above } y \\ 0, & \text{otherwise} \end{cases} \\ d_{ij} &= \begin{cases} 1, & \text{if } (i, j) \text{ crosses the cut location } (x) \text{ below } y+h \\ 0, & \text{otherwise.} \end{cases} \end{aligned}$$

For  $h_G \leq 1$ , the solution to the following MILP is a worst-case cut:

$$\begin{aligned} \max \quad & \sum_{(i,j)} p_{ij}c_{ij}z_{ij} \\ \text{such that} \quad & (r_j - l_i)x - (y - l_i) \geq u_{ij} - 1 \quad \forall i, j \\ & (y + h - l_i) - (r_j - l_i)x \geq d_{ij} - 1 \quad \forall i, j \\ & u_{ij} + d_{ij} \geq 2z_{ij} \quad \forall i, j \\ & 0 \leq x \leq 1 \\ & -h \leq y \leq h_G \\ & u_{ij}, d_{ij}, z_{ij} \in \{0, 1\}. \end{aligned}$$

Solving integer programs can be computationally intensive, yet the geographical (geometric) nature of the BGNI Problem lends itself to relatively low-complexity algorithms (see Section V). Although we initially focus only on the TEC measure, variants of the BGNI Problem can be formulated

<sup>2</sup>The two-terminal reliability between two nodes is the probability they remain connected after random independent link failures [32].

<sup>3</sup>For performance measure TEC, the worst-case cut obtains a maximum value, while for the rest, it obtains a minimum value.

for performance measures ATTR, MFST, and AMF (by definition, when computing these measures, we assume that  $p_{ij} \in \{0, 1\} \forall i, j$ ). In the bipartite model, the worst-case cut under some of these measures is trivial. However, in the general model, a worst-case cut is nontrivial.

### B. General Model

The general geometric graph model contains  $N$  nonoverlapping nodes on a plane. Let the location of node  $i$  be given by the cartesian pair  $[x_i, y_i]$ . Assume the points representing the nodes are in general form, that is, no three points are collinear. Denote a link from node  $i$  to node  $j$  as  $(i, j)$ , and let  $(i, j)$  be represented by a line segment from  $[x_i, y_i]$  to  $[x_j, y_j]$ .<sup>4</sup> We define  $p_{ij}$  as the probability of  $(i, j)$  existing and  $c_{ij}$  as the capacity of  $(i, j)$ , where  $c_{ij} \in [0, \infty)$ . We again assume that  $c_{ij}p_{ij} > 0$  for some  $i$  and  $j$ . We now define two types of cuts and the corresponding problems.

When dealing with *arbitrary line segment cuts*, we assume that a disaster results in a line segment cut of length  $h$ , which starts at  $[x, y]$  and contains the point  $[v, w]$  (with  $[x, y] \neq [v, w]$ ). We define this cut as  $\text{cut}_h([x, y], [v, w])$  (note there can be infinitely many ways to express a single cut). A cut removes all links that intersect it. For brevity, we sometimes denote the worst-case cut  $\text{cut}_h([x^*, y^*], [v^*, w^*])$  as  $\text{cut}_h^*$ . We now define the following problem and demonstrate its formulation.

1) *Geographical Network Inhibition by Line Segments (GNIL) Problem*: Given a graph, cut length, link probabilities, and capacities, find a worst-case cut under performance measure TEC.

We define the following (0,1) variable:

$$z_{ij}([x, y], [v, w]) = \begin{cases} 1, & \text{if } (i, j) \text{ is removed by } \text{cut}_h([x, y], [v, w]) \\ 0, & \text{otherwise.} \end{cases}$$

A solution to the following GNIL optimization problem is a worst-case cut:

$$\begin{aligned} \max \quad & \sum_{(i,j)} p_{ij} c_{ij} z_{ij}([x, y], [v, w]) \\ \text{such that} \quad & [x, y] \neq [v, w] \\ & \sqrt{(x-v)^2 + (y-w)^2} \leq h \\ & x_i \leq x \leq x_j \text{ for some } i \text{ and } j \\ & y_i \leq y \leq y_j \text{ for some } i \text{ and } j. \end{aligned} \quad (2)$$

When dealing with *circular cuts*, we assume that a disaster results in a cut of radius  $r$ , which is centered at  $[x, y]$ . We define this cut as  $\text{cut}_r(x, y)$ . Such a cut removes all links that intersect it (including the interior of the disk). We call the set of points for which the Euclidean distance is  $r$  away from  $[x, y]$  the boundary of  $\text{cut}_r(x, y)$ . For brevity, we sometimes denote the worst-case cut  $\text{cut}_r(x^*, y^*)$  as  $\text{cut}_r^*$ . We now define the following problem and demonstrate its formulation.

<sup>4</sup>Notice that the assumption that links are represented by line segments is an approximation of the real deployments (e.g., [22]) in which links may not be linear.

Fig. 3. Example of a complete bipartite graph with  $N = 8$ .

2) *Geographical Network Inhibition by Circular Cuts (GNIC) Problem*: Given a graph, cut radius, link probabilities, and capacities, find a worst-case circular cut under performance measure TEC.

We define the following (0,1) variable:

$$z_{ij}(x, y) = \begin{cases} 1, & \text{if } (i, j) \text{ is removed by } \text{cut}_r(x, y) \\ 0, & \text{otherwise.} \end{cases}$$

A solution to the following GNIC optimization problem is the center of a worst-case cut:

$$\begin{aligned} \max \quad & \sum_{(i,j)} p_{ij} c_{ij} z_{ij}([x, y]) \\ \text{such that} \quad & x_i \leq x \leq x_j \text{ for some } i \text{ and } j \\ & y_i \leq y \leq y_j \text{ for some } i \text{ and } j. \end{aligned} \quad (3)$$

Similar GNIL and GNIC problems can be formulated for performance measures ATTR, MFST, and AMF (for these measures, we assume that  $p_{ij} \in \{0, 1\} \forall i, j$ ). For example, under MFST, flow conservation constraints should be added to the set of constraints, the flow through links for which  $z_{ij}([x, y], [v, w]) = 1$  is 0, and the flow between  $s$  and  $t$  has to be maximized. In Sections VI and VII, we use the geometric nature of the GNIL and GNIC problems to show that under all these measures, we only need to check a polynomial number of locations in order to find a worst-case cut.

## IV. MOTIVATING EXAMPLE

In this section, we consider a simple case of the bipartite model in which the network is represented as a complete bipartite graph, each side has  $N/2$  nodes,  $p_{ij} = 1$ , and  $c_{ij} = 1$ . We also place nodes evenly on each side such that they are separated by distance  $a$ . An example is shown in Fig. 3. We first obtain a lower bound for the BGNI problem by considering cuts down the center. Then, we provide numerical results for the BGNI problem.

### A. Lower Bound

In this simple model, we can bound the value of TEC for the worst-case cut by considering cuts with endpoints at  $x = 0.5$ . In the very center of the graph, there is an intersection of  $N/2$  links.  $a/2$  units vertically up and down from this point, an additional  $(N/2) - 1$  links intersect. Another  $a/2$  units up and down from these points, another  $(N/2) - 2$  links intersect. This pattern continues until all of the links are included. Therefore, the capacity removed by a worst-case cut of height  $h$  for  $h \leq h_G$  is lower-bounded by

$$\frac{N}{2} + \sum_{i=1}^{\lfloor \frac{2h}{a} \rfloor} \left( \frac{N}{2} - 1 - \left\lfloor \frac{i-1}{2} \right\rfloor \right). \quad (4)$$

Fig. 4. Number of links intersected (TEC) by a worst-case cut  $[\text{cut}_h(x^*, y^*)]$  as a function of the cut height ( $h$ ) in a bipartite graph with 15 nodes on each side ( $N = 30$ ).

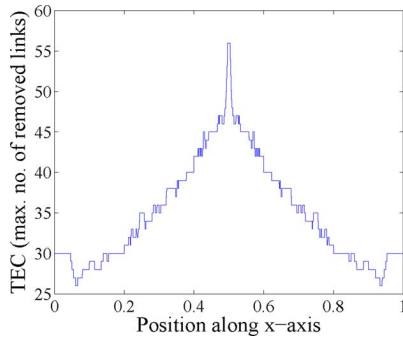

Fig. 5. Maximum number of removed links (TEC) as a function of the  $x$ -location of the cut for  $h = 1.6$ . Note that the results were relatively monotonic, with the worst-case cut appearing at the center.

### B. Intuition From Numerical Results

We now describe numerical solutions obtained for the BGNI problem (1).<sup>5</sup> We obtained solutions for a network with 15 nodes on each side ( $N = 30$ ) and with  $a = 1$  ( $h_G = 14$ ). Fig. 4 describes the values of TEC under the worst-case cut for different cut heights,  $h$  (notice that for  $p_{ij} = 1$  and  $c_{ij} = 1$ , TEC is equivalent to the number of removed links). The result is identical to the lower bound for the center cuts in (4). This implies that a worst-case cut is located at the center of the graph.

Next, we study the effect of the horizontal cut location on TEC (the number of removed links) on the same network. Figs. 5 and 6 illustrate the maximum number of removed links versus the horizontal ( $x$ ) position of the cut on the network. For a given cut height ( $h$ ), the maximum number of removed links at each horizontal position ( $x$ ) is not decreasing monotonically as we move away from the center. With  $h = 1.6$ , the results were relatively monotonic, with the worst-case cut appearing at the center while the number of removed links more or less descends from there (Fig. 5). When the cut height is reduced to 0.1, significant local maxima begin to appear (Fig. 6). It seems the smaller the cut height, the more pronounced these local maxima are. This possibly results from large intersections of links crossing at different horizontal locations in the graph. Small cuts can cut these off-center intersections and remove a

<sup>5</sup>These solutions were initially obtained using MATLAB's genetic algorithms and later on verified using the algorithm described in Section V.

Fig. 6. Maximum number of removed links (TEC) as a function of the  $x$ -location of the cut for  $h = 0.1$ . Note the two "spikes" in the function at  $x \approx 0.3$  and  $x \approx 0.7$ .

- 

large number of links, but these small cuts are not as effective elsewhere in the graph (where links do not intersect).

The results above motivate us to analytically study the effect of the cut location on the removed capacity. In the following sections, we focus on developing polynomial-time algorithms for identifying a worst-case cut.

### V. WORST-CASE CUTS—BIPARTITE MODEL

In this section, we present an  $O(N^6)$  algorithm for solving the BGNI problem. The main underlying idea is that the algorithm only needs to consider cuts that have an endpoint on a link intersection or a node. Before proceeding, we note that the objective function takes on a finite number of bounded values. This leads to the following observation.

1) *Observation 1:* There always exists an optimal solution to (1) (i.e., a worst-case cut).

We present the algorithm that finds a worst-case cut. It can be seen that the complexity of Algorithm WCBG is  $O(N^6)$ . This results from the following facts: 1) links are line segments, and a pair of line segments can have at most one intersection point (no three nodes are collinear), resulting in at most  $O(N^4)$  link intersections; 2) there are two candidate cuts per link intersection or node (cuts have two endpoints), and therefore, the total number of candidate cuts is at most  $O(N^4)$ ; 3) since evaluating

Fig. 7. Example showing  $(i_\omega, j_\omega)$  and  $(i_\alpha, j_\alpha)$ .  $(i_\alpha, j_\alpha)$  is the lowest link intersected by the cut, and this intersection is at  $[x_\alpha, y_\alpha]$ .  $(i_\omega, j_\omega)$  are the highest links intersected by the cut, and this intersection is at  $[x_\omega, y_\omega]$ . Note  $(i_\omega, j_\omega)$  is not unique.

$\mathbf{1}_{y_k \leq (r_j - l_i)x_k + l_i} \mathbf{1}_{y_k + h \geq (r_j - l_i)x_k + l_i}$  (Line 8) takes  $O(1)$  time and has to be evaluated for all  $(i, j)$ , finding the capacity of a candidate cut takes  $O(N^2)$ .<sup>6</sup>

We now use a number of steps to prove the following theorem.

**Theorem 1:** Algorithm WCBG finds a worst-case cut that is a solution to the optimization problem in (1).

Before proving the theorem, we introduce some useful terminology and prove two supporting lemmas. If  $\text{cut}_h(x, y)$  intersects any links, the links that are intersected closest to the endpoint  $[x, y]$  are denoted by  $(i_\alpha, j_\alpha)$ , and the point where they intersect the cut is denoted by  $[x_\alpha, y_\alpha]$  (see Fig. 7 for an example). Let those links that intersect  $\text{cut}_h(x, y)$  farthest from the endpoint  $[x, y]$  be given by  $(i_\omega, j_\omega)$ , and let the point where they intersect the cut be given by  $[x_\omega, y_\omega]$ . Note that  $(i_\omega, j_\omega)$  or  $(i_\alpha, j_\alpha)$  need not be unique. This is because  $[x_\omega, y_\omega]$  or  $[x_\alpha, y_\alpha]$  can be a link intersection. It should be noted that since the model assumes that there exists a link with  $p_{ij}c_{ij} > 0$  for some  $i$  and  $j$ , all worst-case cuts must intersect at least one link. This implies  $(i_\omega, j_\omega)$  and  $(i_\alpha, j_\alpha)$  exist for all worst-case cuts.

**Lemma 1:** If there exists a worst-case cut,  $\text{cut}_h(x^*, y^*)$ , such that either  $(i_\omega, j_\omega)$  is not unique,  $(i_\alpha, j_\alpha)$  is not unique, or  $x^* \in \{0, 1\}$ , then there exists a worst-case cut that has an endpoint on a node or a link intersection.

*Proof:* Assume  $(i_\alpha, j_\alpha)$  is not unique or  $x^* \in \{0, 1\}$  ( $[x^*, y_\alpha]$  is a node or link intersection). Consider  $\text{cut}_h(x^*, y_\alpha)$ , which is a “slid up” version of the worst-case cut  $\text{cut}_h(x^*, y^*)$ .  $\text{cut}_h(x^*, y_\alpha)$  intersects at least the same links as  $\text{cut}_h(x^*, y^*)$  since, by definition of  $[x_\alpha, y_\alpha]$ , there exist no links at  $x^*$  from  $y^*$  to  $y_\alpha$ . Thus,  $\text{cut}_h(x^*, y_\alpha)$  is also a worst-case cut and has an endpoint on a node or link intersection. For an example, see Fig. 8. The case where  $(i_\omega, j_\omega)$  is not unique is analogous except that  $\text{cut}_h(x^*, y_\omega - h)$ , which is a “slid down” version of  $\text{cut}_h(x^*, y^*)$ , is considered. ■

**Lemma 2:** If there exists a worst-case cut,  $\text{cut}_h(x^*, y^*)$ , such that both  $(i_\omega, j_\omega)$  and  $(i_\alpha, j_\alpha)$  are unique, then there exists a worst-case cut that has an endpoint on a link intersection or node.

*Proof:* See the Appendix.

Basically, according to Lemma 2, if  $(i_\omega, j_\omega)$  and  $(i_\alpha, j_\alpha)$  are both unique for a worst-case cut, we can find another worst-case cut such that it has at least one endpoint on a link intersection or node (see Fig. 9).

<sup>6</sup>Computational geometry results can probably be used to reduce the complexity of Algorithm WCBG. Particularly, [10] (based on [5]) enables counting and locating all the intersections of  $N^2$  line segments in  $O(N^2 \log N + I)$  time, where  $I$  is the number of line segment intersections. A modified version of the algorithm of [10] can be used within Algorithm WCBG.

Fig. 8. Example showing how  $\text{cut}_h(x^*, y_\alpha)$  is a “slid up” version of  $\text{cut}_h(x^*, y^*)$ .  $\text{cut}_h(x^*, y_\alpha)$ , which has an endpoint on a link intersection, is guaranteed to intersect every link  $\text{cut}_h(x^*, y^*)$  does because there exist no links at  $x^*$  from  $y^*$  to  $y_\alpha$ .

Fig. 9.  $\text{cut}_h(x^*, y^*)$  is a worst-case cut and has a unique  $(i_\omega, j_\omega)$  and  $(i_\alpha, j_\alpha)$ . From this, we are able to find  $\text{cut}_h(x', y_\alpha(x'))$ , a worst-case cut that has an endpoint on a link intersection.

Using the above lemmas, we now prove Theorem 1.

*Proof of Theorem 1:* Since  $(i_\omega, j_\omega)$  and  $(i_\alpha, j_\alpha)$  exist for all worst-case cuts, Lemmas 1 and 2 imply that we need only check cuts that have endpoints at nodes or link intersections to find a worst-case cut. Algorithm 1 checks all possible nodes and intersections as endpoints, and therefore will necessarily also find a worst-case cut. ■

We note that although algorithm WCBG finds a worst-case cut, there may be other worst-case cuts with the same value. The endpoints of these cuts do not necessarily have to be on a link intersection or a node. However, there cannot be a cut with a higher value than the one obtained by the algorithm.

## VI. WORST-CASE LINE SEGMENT CUT—GENERAL MODEL

In this section, we present a polynomial-time algorithm for finding the solution of the GNIL Problem, i.e., for finding a worst-case line segment cut in the general model. We show that we only need to consider a polynomial-sized subset of all possible cuts. We first focus on the TEC performance measure and then discuss how to obtain a worst-case cut for other measures. Our methods are similar to the approach for solving the BGNI Problem, described in Section V. In this section, a worst-case cut refers to a worst-case *line segment* cut.

### A. TEC Performance Measure

Before proceeding, note that the objective function in (2) takes on a finite number of bounded values. This leads to the following observation.

1) *Observation 2:* There always exists an optimal solution to (2) (i.e., a worst-case cut).

We present an algorithm that finds a worst-case line segment cut under the TEC measure in the general model. This algorithm considers all cuts that: 1) have an endpoint on a link intersection and contain a node not at the intersection; 2) have an endpoint on a link intersection and another endpoint on a link; 3) contain two distinct nodes and have an endpoint on a link; and 4) contain a node and have both endpoints on links.

---

**Algorithm 2:** Worst-Case Line Segment Cut in the General Model (WLGGM)
 

---

```

1: input:  $h$ , length of cut
2: worstCaseCapacityCut  $\leftarrow 0$ 
3:  $L \leftarrow \{\}$ 
4: for every link intersection  $[x_k, y_k]$  do
5:   for every node  $i$  such that  $[x_i, y_i] \neq [x_k, y_k]$  do
6:      $L = L \cup \{\text{cut that has an endpoint at } [x_k, y_k] \text{ and}$ 
7:        $\text{contains } [x_i, y_i]\}$ 
8:   for every  $(i, j)$  do
9:      $L = L \cup \{\text{cuts that have an endpoint at } [x_k, y_k] \text{ and}$ 
10:       $\text{another endpoint on } (i, j)\}$ 
11:   for every  $(i, j)$  and node  $k$  do
12:     for every node  $l$  such that  $k \neq l$  do
13:        $L = L \cup \{\text{cuts that have an endpoint on } (i, j) \text{ and}$ 
14:         $\text{contain } [x_k, y_k] \text{ and } [x_l, y_l]\}$ 
15:     for every  $(m, n)$  do
16:        $L = L \cup \{\text{cuts that have an endpoint on } (i, j),$ 
17:         $\text{another endpoint on } (m, n), \text{ and contain } [x_k, y_k]\}$ 
18:   for every  $\text{cut}_h([x_k, y_k], [v_k, w_k]) \in L$  do
19:     call evaluateCapacityofCut( $x_k, y_k, v_k, w_k$ )
20:   return  $\text{cut}_h^*$ 
21: Procedure evaluateCapacityofCut( $x_k, y_k, v_k, w_k$ )
22: capacityCut  $\leftarrow 0$ 
23: for every  $(i, j)$  do
24:   if  $z_{ij}([x_k, y_k], [v_k, w_k]) = 1$  then
25:     capacityCut  $\leftarrow$  capacityCut +  $c_{ij}p_{ij}$ 
26:   if capacityCut  $\geq$  worstCaseCapacityCut then
27:      $\text{cut}_h^* \leftarrow \text{cut}_h([x_k, y_k], [v_k, w_k])$ 
28:   worstCaseCapacityCut  $\leftarrow$  capacityCut

```

---

We now use a number of steps to prove the following theorem.

*Theorem 2:* Algorithm WLGGM has a running time of  $O(N^8)$  and finds a worst-case line segment cut that is a solution to the GNIL Problem.

Before proving the theorem, we present some lemmas to reduce the set of candidate worst-case cuts.

*Lemma 3:* There exists a worst-case cut that contains a node or has an endpoint at a link intersection.

*Proof:* Let  $\text{cut}_h^*$  be a worst-case cut with endpoints given by  $[x^*, y^*]$  and  $[v^*, w^*]$ . We now define some useful terminology. Let the links that intersect  $\text{cut}_h^*$  closest to the endpoint  $[x^*, y^*]$  be given by  $(i_\alpha, j_\alpha)$ , and let the closest point to  $[x^*, y^*]$  where  $(i_\alpha, j_\alpha)$  intersects  $\text{cut}_h^*$  be given by  $[x_\alpha, y_\alpha]$ . Let those links that intersect  $\text{cut}_h^*$  farthest from the endpoint  $[x^*, y^*]$  be given by  $(i_\omega, j_\omega)$ , and let the closest point to  $[v^*, w^*]$  where  $(i_\omega, j_\omega)$  intersects  $\text{cut}_h^*$  be given by  $[x_\omega, y_\omega]$ . We consider two cases, one where either  $(i_\alpha, j_\alpha)$  or  $(i_\omega, j_\omega)$  are not unique, and the other where  $(i_\alpha, j_\alpha)$  and  $(i_\omega, j_\omega)$  are unique.

In the first case, either  $(i_\alpha, j_\alpha)$  or  $(i_\omega, j_\omega)$  are not unique for  $\text{cut}_h^*$ . Without loss of generality, we assume  $(i_\alpha, j_\alpha)$  is not unique. We consider  $\text{cut}_h'$ , which is a translated version of  $\text{cut}_h^*$  such that it has an endpoint on  $[x_\alpha, y_\alpha]$  and on  $[v^* + x_\alpha - x^*, w^* + y_\alpha - y^*]$ . Since there exist no links between  $[x^*, y^*]$  and  $[x_\alpha, y_\alpha]$ , we know  $\text{cut}_h'$  intersects at least as many links as

Fig. 10.  $\text{cut}_h'$  contains a node as well as intersects all links that  $\text{cut}_h^*$  does.

$\text{cut}_h^*$  and thus is a worst-case cut that satisfies the lemma. Fig. 8 shows the analogous case for the bipartite model.

In the second case,  $(i_\alpha, j_\alpha)$  and  $(i_\omega, j_\omega)$  are both unique for  $\text{cut}_h^*$ . If  $\text{cut}_h^*$  contains a node, the lemma is satisfied. In the following, assume  $\text{cut}_h^*$  does not contain a node. Now we consider  $\text{cut}_h'([x^* + a, y^* + b], [v^* + a, w^* + b])$  and  $\text{cut}_h''([x^* - c, y^* - d], [v^* - c, w^* - d])$  to be translated versions of  $\text{cut}_h^*$  such that: 1)  $\text{sign}(a) = \text{sign}(c)$  and  $\text{sign}(b) = \text{sign}(d)$ ; 2) there does not exist any nodes in the parallelogram defined by  $\text{cut}_h^*$  and  $\text{cut}_h'$  (which we denote “parallelogram  $B$ ”) except those contained in  $\text{cut}_h'$  and in the parallelogram defined by  $\text{cut}_h^*$  and  $\text{cut}_h''$  (which we denote “parallelogram  $C$ ”) except those contained in  $\text{cut}_h''$ ; and 3) no link intersects  $(i_\alpha, j_\alpha)$  or  $(i_\omega, j_\omega)$  in either parallelogram except on  $\text{cut}_h'$  or  $\text{cut}_h''$ . Since a node does not exist within the interior of either parallelogram, all links intersected by  $\text{cut}_h^*$  must also cut one of the other three edges of each parallelogram.

Now choose the maximum  $a$  and  $c$  such that the edge  $([x^*, y^*], [x^* + a, y^* + b])$  of parallelogram  $B$  and the edge  $([x^*, y^*], [x^* - c, y^* - d])$  of parallelogram  $C$  are both parallel to the link  $(i_\alpha, j_\alpha)$  and the parallelograms satisfy the constraints in the previous paragraph. This implies both  $\text{cut}_h'$  and  $\text{cut}_h''$  contain a node or contain a point where  $(i_\alpha, j_\alpha)$  or  $(i_\omega, j_\omega)$  intersects a link. Since  $(i_\alpha, j_\alpha)$  is parallel to both edges  $([x^*, y^*], [x^* + a, y^* + b])$  and  $([x^*, y^*], [x^* - c, y^* - d])$  and since  $(i_\omega, j_\omega)$  can cut at most one of the edges  $([v^*, w^*], [v^* + a, w^* + b])$  and  $([v^*, w^*], [v^* - c, w^* - d])$  or be parallel to them (as they both lay on the same straight line), we know at least one of  $\text{cut}_h'$  or  $\text{cut}_h''$  intersects the same links that are intersected by  $\text{cut}_h^*$ . Therefore, we can choose  $a, b, c,$  and  $d$  such that either  $\text{cut}_h'$  or  $\text{cut}_h''$  is a worst-case cut and: 1) contains a node (Fig. 10); or 2) contains a point where  $(i_\alpha, j_\alpha)$  or  $(i_\omega, j_\omega)$  intersects a link. In the latter case, we can translate this worst-case cut in a similar fashion to the first case to construct a worst-case cut that satisfies the lemma. ■

We now consider two cases of worst-case cuts. The first case is a worst-case cut that has an *endpoint* at a link intersection. The second case is a worst-case cut that *contains* a node. In both cases, let the node or link intersection that is in the cut be denoted by  $A$ . Lemma 4 handles the first case where  $A$  can be considered as a link intersection.

*Lemma 4:* If there exists a worst-case cut that has an endpoint on point  $A$ , then: 1) there exists a worst-case cut that has an endpoint on  $A$  and has its other endpoint on a link; or 2) there exists a worst-case cut that has an endpoint on  $A$  and contains a node that is not  $A$ .

*Proof:* Assume there exists a worst-case cut with endpoint  $A$ , denoted by  $\text{cut}_h^*$ . Therefore, the other endpoint of  $\text{cut}_h^*$  must be on a circle of radius  $h$ . Denote by  $\theta$  the angle of  $\text{cut}_h^*$  in some coordinate system. Denote by  $\theta_i$  the angles from  $A$  to all nodes inside the circle and all intersections of links

Fig. 11. Translate an endpoint of  $\text{cut}_h^*$  along the circumference of the circle until the cut intersects a node or the translated endpoint intersects a link; call this new cut  $\text{cut}'_h$ . Since every link which intersects  $\text{cut}_h^*$  intersects  $\text{cut}'_h$ ,  $\text{cut}'_h$  is a worst-case cut.

Fig. 12. Translate  $\text{cut}_h^*$  along the line that contains it until one of its endpoints intersects a link. We call this new cut  $\text{cut}'_h$ .  $\text{cut}'_h$  intersects all links  $\text{cut}_h^*$  intersects.

with the circle (including links tangent to the circle). Choose  $\theta' = \theta_j$  such that  $j = \arg \min_i |\theta - \theta_i|$ . Choose  $\text{cut}'_h$  to be the cut with endpoint at  $A$  and having length  $h$  and angle  $\theta'$ . By definition of  $\theta'$  and the  $\theta_i$ 's, all links intersecting  $\text{cut}_h^*$  must also intersect  $\text{cut}'_h$  (because between  $\theta$  and  $\theta'$  no link intersects with the circle and there exists no node within the interior of that sector). Thus,  $\text{cut}'_h$  is a worst-case cut (see Fig. 11). ■

The following two lemmas handle the second case where  $A$  can be considered as a node.

**Lemma 5:** If there exists a worst-case cut that contains point  $A$ , then there exists a worst-case cut that contains  $A$  and has an endpoint on some link.

*Proof:* Let  $\text{cut}_h^*$  be a worst-case cut that intersects  $A$  with endpoints given by  $[x^*, y^*]$  and  $[v^*, w^*]$ . Let the links that intersect  $\text{cut}_h^*$  closest to the endpoint  $[x^*, y^*]$  be given by  $(i_\alpha, j_\alpha)$ , and let the closest point to  $[x^*, y^*]$  where  $(i_\alpha, j_\alpha)$  intersects  $\text{cut}_h^*$  be given by  $[x_\alpha, y_\alpha]$ . We consider  $\text{cut}'_h$ , which is a translated version of  $\text{cut}_h^*$  such that it has endpoints at  $[x_\alpha, y_\alpha]$  and at  $[v^* + x_\alpha - x^*, w^* + y_\alpha - y^*]$ . Since there exist no links between  $[x^*, y^*]$  and  $[x_\alpha, y_\alpha]$ , and because the same line contains both  $\text{cut}_h^*$  and  $\text{cut}'_h$ , we know that every link that intersects  $\text{cut}_h^*$  also intersects  $\text{cut}'_h$  in the same location (see Fig. 12). Thus,  $\text{cut}'_h$  is a worst-case cut that contains  $A$  and has an endpoint on a link (this endpoint is  $[x_\alpha, y_\alpha]$ ). ■

**Lemma 6:** If there exists a worst-case cut that contains  $A$  and has an endpoint on a link, then there exists a worst-case cut that contains  $A$ , has an endpoint on a link, and at least one of the following holds: 1) the cut contains a node that is not  $A$ ; 2) one of the cut endpoints is also a link intersection that is not  $A$ ; or 3) the cut has both endpoints on links.

*Proof:* Let  $\text{cut}_h^*$  be a worst-case cut such that it contains  $A$  and has an endpoint on a link. If  $\text{cut}_h^*$  has an endpoint on  $A$ , then Lemma 4 implies Lemma 6. Assume  $\text{cut}_h^*$  contains  $A$  and has an endpoint on a link and does *not* have an endpoint on  $A$ . Denote the link that contains this endpoint by  $L$ , and one of its endpoints by  $[x_1, y_1]$ . Denote the point at which  $\text{cut}_h^*$  intersects  $L$  by  $[x_0, y_0]$ . Now translate the endpoint of  $\text{cut}_h^*$  along  $L$

Fig. 13. Translate an endpoint of  $\text{cut}_h^*$  right along  $L$  until it intersects a link intersection. This new cut is the  $\text{cut}'_h$  on the right. We can also translate an endpoint of  $\text{cut}_h^*$  left along  $L$  until it intersects a node. This new cut is the  $\text{cut}'_h$  on the left.

Fig. 14. Translate an endpoint of  $\text{cut}_h^*$  along  $L$  until it can no longer intersect the bottom link. This new cut is  $\text{cut}'_h$ .

so that this new cut still contains  $A$ . That is, consider the cut, of length  $h$ , with endpoint at  $[ax_1 + (1-a)x_0, ay_1 + (1-a)y_0]$  and passing through  $A$ , for  $0 \leq a \leq 1$ . For  $a = 0$ , this is just  $\text{cut}_h^*$ . We increase  $a$  until a new cut, called  $\text{cut}'_h$ , either has an endpoint that is  $h$  away from  $A$  (we cannot translate further) or  $\text{cut}'_h$  can no longer satisfy  $\sum_{(i,j)} p_{i,j} c_{i,j} \text{cut}'_h = \sum_{(i,j)} p_{i,j} c_{i,j} \text{cut}_h^*$ . In the first case, the cut has both endpoints on links. In the second case,  $\text{cut}'_h$  satisfies at least one of the following:  $\text{cut}'_h$  has an endpoint on  $L$  that is a link intersection (considered in Lemma 4),  $\text{cut}'_h$  intersects a node that is not  $A$ , or  $\text{cut}'_h$  has an endpoint on  $L$  and the other endpoint on a link. The first two possibilities are demonstrated in Fig. 13. Fig. 14, which demonstrates the third possibility, shows  $\text{cut}'_h$  that contains  $A$  and has both endpoints on links. ■

Using the lemmas above, we now prove Theorem 2.

*Proof of Theorem 2:* The lemmas presented in this section imply we only need to consider a polynomially sized set of cuts. By Lemma 3, there are two possible cases of worst-case cuts. The first case is a worst-case cut that has an endpoint at a link intersection. The second case is a worst-case cut that contains a node. In the first case, Lemma 4 implies that for every link intersection,  $O(N^4)$ , there exists a possible worst-case cut for every link and node,  $O(N^2)$ . In the second case, Lemmas 5 and 6 imply that for every node-link pair ( $A$  and some link  $L$ ),  $O(N^3)$ , there exist several possible worst-case cuts for every node and link,  $O(N^2)$ . Since naively checking each cut for the total cut capacity takes  $O(N^2)$ , the algorithm has a total running time of  $O(N^8)$  (the first case provides the greatest running time). ■

It should be noted that similarly to the bipartite case, although the algorithm finds a worst-case cut, there may be other worst-case cuts with the same value. However, there cannot be a cut with a better value than the one obtained by the algorithm.

## B. ATTR, MFST, and AMF Performance Measures

As mentioned in Section III-B, the formulation of the GNIL Problem, presented in (2), should be slightly modified in order to

accommodate the ATTR, MFST, and AMF performance measures. We now briefly discuss how the algorithm has to be modified in order to obtain results for these problems. In Section VIII, we present numerical results obtained using these modified algorithms. Using the above-mentioned lemmas and theorem, it is easy to show that only a polynomial number of candidate cuts need to be checked in order to find the worst-case cut under any of the performance measures. This is due to the fact that the performance measures are monotonic. Therefore, any additional link removed/added only increases/decreases the measure, and all the arguments supporting our lemmas still hold.

For each potential cut, some links and/or nodes are removed. Hence, one has to update the network adjacency matrix. Then, different operations have to be performed for each measure.

- ATTR: If the network is fully connected, the value of ATTR is 1. Otherwise, one has to sum over all components the value of  $k(k-1)$ , where  $k$  is the number of nodes in each of the components. Then, the sum has to be divided by  $N(N-1)$ . In order to verify connectivity or to count the number of nodes in each component, the Breadth First Search (BFS) algorithm or the adjacency matrix eigenvalues and eigenvectors can be used.
- MFST: Run a max-flow algorithm (e.g.,  $O(N^3)$  [1]).
- AMF: Run a max-flow algorithm for every node pair.

## VII. WORST-CASE CIRCULAR CUT—GENERAL MODEL

In this section, we present a polynomial-time algorithm for finding a solution of the GNIC Problem, i.e., for finding a worst-case circular cut in the general model. We show that we only need to consider a polynomial-sized subset of all possible cuts. We focus on the TEC performance measure and then briefly discuss how to obtain a worst-case cut for the other performance measures. In this section, a cut refers to a *circular* cut of a particular radius.

Before proceeding, note that the objective function in (3) takes on a finite number of bounded values. This leads to the following observation.

*Observation 3:* There always exists an optimal solution to (3) (i.e., a worst-case cut).

We present an algorithm that finds a worst-case circular cut under the TEC measure in the general model.

*Theorem 3:* Algorithm WCGM has a running time of  $O(N^6)$  and finds a worst-case circular cut which is a solution to the GNIC Problem.

Before proving the theorem, we present a useful lemma about cuts and line segments and then present some lemmas to reduce the set of candidate cuts.

*Lemma 7:* If a line segment intersects only the boundary of a cut, then the line segment and cut intersect at exactly one point.

*Proof:* Proof by contradiction. Assume a line segment intersects only the boundary of a cut and this intersection contains more than one point. Since a line segment and a cut region are both convex, their intersection must be convex as well. However, we assumed at least two points on the boundary of the cut are in the intersection. The fact that the intersection must be convex implies the chord connecting these two points must be in the intersection as well. Since part of the chord is in the interior of the cut, this leads to a contradiction. ■

Fig. 15. Example illustrating Lemma 8.  $\text{cut}_r'$  is a translated version of  $\text{cut}_r^*$  such that  $[x', y']$  lies on the line that contains the intersected link and  $\text{cut}_r'$  intersects the link at exactly one point (recall  $[x', y']$  is the center of  $\text{cut}_r^*$ ).

---

### Algorithm 3: Worst-Case Circular Cut in the General Model (WCGM)

---

```

1: input:  $r$ , radius of cut
2:  $\text{worstCaseCapacityCut} \leftarrow 0$ 
3:  $L \leftarrow \{\}$ 
4: for every  $(i, j)$  do
5:    $L = L \cup \{\text{cuts that intersect } (i, j) \text{ at exactly one point}$ 
    $\text{and are centered on the line which contains } (i, j)\}$ 
6:   for  $(k, l)$  such that  $(i, j) \neq (k, l)$  do
7:     if  $(i, j)$  is parallel to  $(k, l)$  then
8:        $L = L \cup \{\text{cuts that contain node } i \text{ or } j \text{ on its}$ 
        $\text{boundary and intersect } (k, l) \text{ at exactly one}$ 
        $\text{point}\}$ 
9:     else
10:       $L = L \cup \{\text{cuts that intersect } (i, j) \text{ and } (l, k) \text{ at}$ 
       $\text{exactly one point each such that these points are}$ 
       $\text{distinct}\}$ 
11:   for every  $\text{cut}_r(x_k, y_k) \in L$  do
12:     call  $\text{evaluateCapacityofCut}(x_k, y_k)$ 
13:   return  $\text{cut}_r^*$ 
Procedure evaluateCapacityofCut}(x_k, y_k)
14:  $\text{capacityCut} \leftarrow 0$ 
15: for every  $(i, j)$  do
16:   if  $\text{minimum distance from } (i, j) \text{ to } [x_k, y_k]$  is  $\leq r$  then
17:      $\text{capacityCut} \leftarrow \text{capacityCut} + c_{ij} p_{ij}$ 
18:   if  $\text{capacityCut} \geq \text{worstCaseCapacityCut}$  then
19:      $\text{cut}_r^* \leftarrow \text{cut}_r(x_k, y_k)$ 
20:    $\text{worstCaseCapacityCut} \leftarrow \text{capacityCut}$ 

```

---

*Lemma 8:* If there exists a worst-case cut, denoted by  $\text{cut}_r^*$ , which intersects exactly one link, then there exists a worst-case cut, denoted by  $\text{cut}_r'$ , that intersects this link at exactly one point such that  $[x', y']$  lies on the line that contains the link (recall  $[x', y']$  is the center of  $\text{cut}_r^*$ ).

*Proof:* Since  $\text{cut}_r^*$  is a worst-case cut and only intersects a single link, any cut that intersects the same link is also a worst-case cut. See Fig. 15. ■

*Lemma 9:* If there exists a worst-case cut, denoted by  $\text{cut}_r^*$ , that intersects at least two links, then there exists a worst-case cut, denoted by  $\text{cut}_r'$ , that intersects at least two links at exactly one point each and at least one of the following holds: 1) at least two of the points are distinct and are not diametrically opposite; 2) at least two of the points are distinct and one of them is a node; or 3)  $[x', y']$  lies on a line containing one of the two links.

The proof of this lemma is similar to the proofs of the lemmas in Section VI. Essentially, it is shown that we can translate a

worst-case cut such that it remains a worst-case cut and satisfies the properties in the lemma.

*Proof:* Assume a link that intersects  $\text{cut}_r^*$  has node locations given by  $[x_i, y_i]$  and  $[x_j, y_j]$ . Consider  $\text{cut}_r[x^* + h(x_j - x_i), y^* + h(y_j - y_i)]$ , where  $h$  is the minimum nonnegative value such that only the boundaries of this cut and some link intersect. Denote this translation of  $\text{cut}_r^*$  by  $\text{cut}_r''$ , and note by Lemma 7 this cut must intersect at least one link at exactly one point. Every link that is intersected by  $\text{cut}_r^*$  must intersect  $\text{cut}_r''$  because as a line segment and a cut are continuously translated away from each other, the last nonempty intersection is an intersection of their boundaries. Thus,  $\text{cut}_r''$  is also a worst-case cut. In the proceeding, we consider two cases. In the first case, we assume  $\text{cut}_r''$  intersects at least two links at exactly one point each, and in the second case we assume  $\text{cut}_r''$  intersects exactly one link at exactly one point.

We first consider the case where  $\text{cut}_r''$  intersects at least two links at exactly one point each (in addition to possibly other links that intersect the interior of  $\text{cut}_r''$ ). Denote one of the points by  $A$  and another by  $B$ . If  $A$  and  $B$  are distinct and not diametrically opposite, the conditions in the lemma are satisfied. Now we will consider two subcases. In the first subcase, we assume  $A$  and  $B$  reside in two diametrically opposing points on  $\text{cut}_r''$ , and in the second subcase we assume  $A$  and  $B$  are not distinct. In the first subcase, if either  $A$  or  $B$  is a node, the lemma holds true. If neither  $A$  or  $B$  are nodes, then  $A$  and  $B$  are diametrically opposing points where parallel links are tangent to  $\text{cut}_r''$ . Denote one of these parallel links by  $(i, j)$ . Now consider  $\text{cut}_r[x'' + h(x_j - x_i), y'' + h(y_j - y_i)]$ , where  $h$  is the minimum nonnegative value such that two links intersect only the boundary of this cut at distinct and nondiametrically opposing points, or two links intersect only the boundary of this cut and one of these intersection points is a node. Denote this translated cut by  $\text{cut}_r'$ . Now, by Lemma 7, one of the following must hold: either  $\text{cut}_r'$  intersects the parallel links at exactly one point each where one of these points is a node, or a link that intersected the interior of  $\text{cut}_r''$  now intersects  $\text{cut}_r'$  at exactly one point such that  $\text{cut}_r'$  intersects two links at exactly one point each such that they are not diametrically opposite and distinct.

In second subcase, two links intersect  $\text{cut}_r''$  at a single point  $C$ . This implies  $C$  is a node of at least one of these links. Now choose a link with a node given by  $C$  and denote the link by  $(k, l)$ . Let  $\mathbf{p}(t)$  be a continuous parameterized closed curve that is always a distance  $r$  from  $(k, l)$  such that  $\mathbf{p}(0) = [x'', y'']$  and  $\mathbf{p}(t_C)$ , where  $t_C > 0$  is the point on  $\mathbf{p}(t)$  closest to  $C$  that intersects the line containing  $(k, l)$  (see Fig. 16). Additionally, we require that  $\mathbf{p}(t)$  is exactly  $r$  units away from  $C$  for  $0 \leq t \leq t_C$ . Let  $p_x(t)$  and  $p_y(t)$  denote the  $x$ - and  $y$ -components of  $\mathbf{p}(t)$ , respectively. Since  $\text{cut}_r''$  intersects  $C$ , we know  $[x'', y'']$  is on a semicircular-shaped part of  $\mathbf{p}(t)$  [these are the only parts of  $\mathbf{p}(t)$  that are  $r$  units away from an endpoint of  $(k, l)$ ]. Now consider  $\text{cut}_r[p_x(t), p_y(t)]$ , where  $t$  is the minimum value such that two links intersect only the boundary of this cut and these intersection points are distinct or  $t = t_C$ . Denote this translated cut by  $\text{cut}_r'$ . If  $t = t_C$ , we know  $\text{cut}_r'$  is centered on the line that contains  $(k, l)$ . As before, we know every link that is intersected by  $\text{cut}_r''$  must intersect  $\text{cut}_r'$ . This is because as a line segment and a cut are continuously translated away from each

Fig. 16. Case in the proof of Lemma 9.  $\text{cut}_r^*$  is first translated in the direction of  $(i, j)$  to become  $\text{cut}_r''$ , which intersects  $(k, l)$  at exactly one point and intersects another link [in this case  $(i, j)$ ] at exactly the same point. Then,  $\text{cut}_r''$  is translated along  $\mathbf{p}(t)$  toward  $\mathbf{p}(t_C)$  to  $\text{cut}_r'$  such that  $[x', y']$  lies on the line that contains  $(k, l)$ .

Fig. 17. Case in the proof of Lemma 9.  $\text{cut}_r^*$  is first translated in the direction of  $(i, j)$  to become  $\text{cut}_r''$ , which intersects  $(k, l)$  at exactly one point. Then,  $\text{cut}_r''$  is translated along  $\mathbf{p}(t)$  to  $\text{cut}_r'$ , where  $(i, j)$  and  $(k, l)$  each intersect  $\text{cut}_r'$  at exactly one point.

other, the last nonempty intersection is an intersection of their boundaries. Also, the links that intersect  $\text{cut}_r''$  at  $C$  remain intersected throughout the translation because  $\text{cut}_r[p_x(t), p_y(t)]$  intersects  $C$  on  $0 \leq t \leq t_C$ . Thus,  $\text{cut}_r'$  is a worst-case cut, and by Lemma 7, we know two links intersect this cut at exactly one point each and one of the following: 1) these points are distinct, and one of them is a node given by  $C$ ; or 2)  $[x', y']$  lies on a line that contains  $(k, l)$  ( $[x', y'] = \mathbf{p}(t_C)$ ).

Now we consider the case where  $\text{cut}_r''$  intersects exactly one link at exactly one point (in addition to other links that intersect the interior of  $\text{cut}_r''$ ). Similarly as above, denote this link by  $(k, l)$ . Let  $\mathbf{p}(t)$  be a continuous parameterized closed curve that is always a distance  $r$  from  $(k, l)$  such that  $\mathbf{p}(0) = [x'', y'']$  (see Fig. 17). Consider  $\text{cut}_r[p_x(t), p_y(t)]$ , where  $t$  is the minimum nonnegative value such that two links intersect only the boundary of this cut (we assume  $\text{cut}_r^*$  intersects at least two links). By Lemma 7, we know these two links intersect this cut at exactly one point each. Therefore, this case reduces to the first case for which we know the lemma holds. ■

**Lemma 10:** There are at most 20 cuts of radius  $r$  that intersect two nonparallel line segment links at exactly one point each such that these points are distinct.

*Proof:* If a link intersects a cut at exactly one point, then either a node of the link intersects the boundary of the cut or the link is tangent to the cut (we call a link tangent to a cut if the line containing the link is tangent to the boundary of the cut). For a particular pair of links, this implies a cut that satisfies the lemma falls into at least one of three cases: 1) the boundary of the cut intersects two distinct nodes (one from each link); 2) the boundary of the cut intersects a node of one link, and the cut is tangent to the other link; or 3) both links are tangent to the cut.

In case 1, by geometry we know there are at most two cuts of radius  $r$  whose boundary contains two distinct nodes. In case 2, given a node and a link, we know by geometry there are at

most two cuts of radius  $r$  that the link is tangent to and whose boundary contains the node. In case 3, given two nonparallel links, the lines containing these segments divide the plane into four pieces. There exist at most one cut tangent to both lines in each of these pieces. Thus, there are at most four cuts tangent to both links. Since for a pair of nonparallel links there are four pairs of nodes to consider (with at most two cuts per pair that satisfy the lemma), four endpoint–link pairs (with at most two cuts per pair that satisfy the lemma), and one link–link pair (with at most four cuts per pair that satisfy the lemma), we know there exists at most 20 cuts that satisfy the lemma. ■

Note that the bound above is a simple upper bound on the number of possible cuts and can possibly be further reduced.

Using the above lemmas, we now prove Theorem 3.

*Proof of Theorem 3:* The lemmas presented in this section imply there exists a worst-case cut that intersects a link at exactly one point such that the center of this cut lies on the line containing this link or there exists a worst-case cut that intersects two links at exactly one point each and at least one of the following: 1) at least two of the points are distinct and are not diametrically opposite; or 2) at least two of the points are distinct and one of them is a node. Algorithm WCGM enumerates all these possible cuts. It considers each link,  $O(N^2)$ , and finds both cuts that intersect the link at exactly one point and whose center lies on the line that contains this link. Then, it considers every combination of two links,  $O(N^4)$ , and if the links are not parallel, it finds every cut (if any exist) that intersects each of the two links at exactly one point such that these points are distinct. By Lemma 10, we know there are at most 20 of these cuts for every pair of links. If the links are parallel, we need only consider cuts that intersect one of the links at exactly one point and whose boundary intersects the other links endpoint. In total, Algorithm WCGM considers  $O(N^4)$  cuts, and since naively checking each cut for the total expected capacity removed takes  $O(N^2)$ , the algorithm has a total running time of  $O(N^6)$ . ■

As mentioned in Section III-B, the formulation of the GNIC Problem, presented in (3), can be slightly modified in order to accommodate the ATTR, MFST, and AMF performance measures. This modification is done in exactly the same way as it was done for the GNIL Problem (see Section VI-B).

It should be noted that we can also consider the case of an *elliptic cut* with fixed axis (that is, no rotation of the ellipse is considered). This disaster model more closely resembles the effect of an EMP. This case can be solved by applying an affine transformation to the network node locations and then running WCGM.

## VIII. NUMERICAL RESULTS

In this section, we present numerical results that demonstrate the use of the algorithms presented in Sections VI and VII. These results shed light on the vulnerabilities of a specific fiber network. Clearly, the algorithms can be used in order to obtain results for additional networks or for a combined fiber plant of several operators. The results were obtained using MATLAB.

We used Algorithm WLGM, presented in Section VI, to compute worst-case cuts under the TEC, ATTR, MFST,

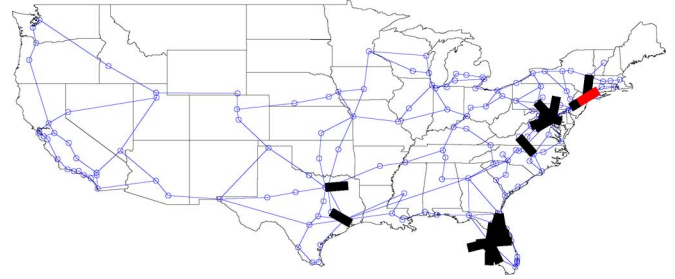

Fig. 18. Line segments cuts optimizing TEC for  $h = 2$ . The gray cuts (red cuts in online color version) maximize TEC, and the black segments are nearly worst-case cuts.

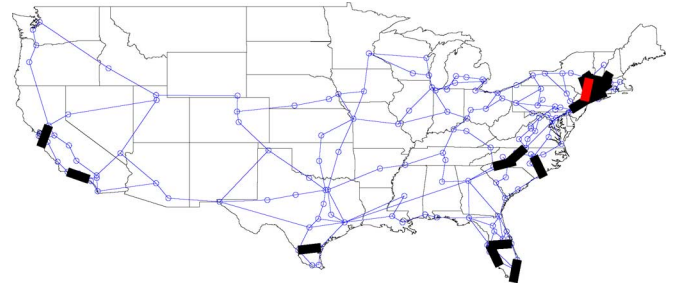

Fig. 19. Line segments cuts optimizing the ATTR for  $h = 2$ . The gray cuts (red cuts in online color version) minimize ATTR, and the black segments are nearly worst-case cuts.

and AMF performance measures for a fiber plant of a major network provider [22]. In all cases, we found that the results are intuitive. We also used Algorithm WCGM, presented in Section VII, to compute worst-case circular cuts under the MFST performance measure for the same fiber plant. We found these circular cuts are in similar locations to their line segment counterparts. All distance units mentioned in this section are in longitude and latitude coordinates (one unit is approximately 60 mi), and for simplicity we assume latitude and longitude coordinates are projected directly to  $[x, y]$  pairs on the plane. We also assume that all the link capacities are equal to 1.

Fig. 18 presents line segment cuts of  $h = 2$  that maximize the TEC performance measure. As expected, we find that TEC is large in areas of high link density, such as areas in Florida, New York, and around Dallas, TX. Fig. 19 presents line segment cuts of  $h = 2$  that minimize the ATTR performance measure. ATTR is smallest where parts of the network are disconnected, such as at the southern tip of Texas, Florida, and most of New England. This is intuitive since in order to decrease the ATTR, the graph must be split, and under a small cut, only small parts of the graph can be removed.

Fig. 20 illustrates line segment cuts of  $h = 4$ , which minimize the MFST performance measure between Los Angeles, CA ( $s$ ) and New York City (NYC) ( $t$ ). Removal of the  $s$  and  $t$  nodes themselves is not considered as this is a trivial worst-case cut. We found that MFST is smallest directly around Los Angeles and NYC as well as in Colorado, Utah, Arizona, New Mexico, and Texas. There are also cuts in the East Coast that completely disconnect NYC from Los Angeles without actually going through NYC. The cuts in the southwest are intuitive since the network in that area is very sparse. In some sense, the

Fig. 20. Line segments cuts optimizing MFST between Los Angeles and NYC for  $h = 4$ . The gray cuts (red cuts in online color version) minimize MFST, and the black segments are nearly worst-case cuts. Cuts that intersect the nodes representing Los Angeles or NYC are not shown.

Fig. 22. Impact of circular cuts of radius 2 on the MFST between Los Angeles and NYC. Gray circles (red circles in online color version) represent cuts that result in MFST = 0, and black circles result in MFST = 1. Cuts that intersect the nodes representing Los Angeles or NYC are not shown.

Fig. 21. Line segments cuts optimizing the AMF for  $h = 2$ . The gray cuts (red cuts in online color version) minimize AMF, and the black segments are nearly worst-case cuts.

Fig. 23. Impact of circular cuts of radius 2 on the MFST between Fort Worth and NYC. Gray circles (red circles in online color version) represent cuts that result in MFST = 0, black circles result in MFST = 1, and light gray circles (yellow circles in online color version) result in MFST = 2. Cuts that intersect the nodes representing Fort Worth or NYC are not shown.

fact that in this case we obtain expected results validates the assumptions and approximations.

We note that different networks (e.g., networks in Europe or Asia) have a different structure than the sparse structure of the southwest U.S. network. In such cases, the solution will not be straightforward. In order to demonstrate it, we will discuss the MSFT measure between NYC and Fort Worth, TX. Before that, we present in Fig. 21 line segment cuts of  $h = 2$  that minimize the AMF performance measure. The AMF values are minimized by cuts in the southwest as well as in Florida and New York.

Finally, we tested how line segment cuts compare to circular cuts. Using Algorithm WCGM, we found circular cuts of  $r = 2$  that minimize the MFST performance measure between Los Angeles and NYC (see Fig. 22). Our results were similar to the line segment case: Worst-case circular cuts were found close to both to Los Angeles and NYC. The southwest area also appeared to be vulnerable, just as in the line segment case.

As mentioned, we tested the MFST measure for circular cuts between Fort Worth and NYC (see Fig. 23). Due to the complexity of the network along the East Coast, the results were less straightforward than in the Los Angeles–NYC case.

Finally, for a circular cut in the fiber plant illustrated in Fig. 1, we computed the maximum value of TEC (removed capacity) as a function of the cut radius. The results are illustrated in Fig. 24. As expected, the maximum value of TEC monotonically increases with the cut radius. This implies that the minimum radius that guarantees a certain level of a specific performance measure (e.g., finding the radius of a circular cut

Fig. 24. Maximum value of TEC as a function of the cut radius for a circular cut in the fiber plant illustrated in Fig. 1.

that ensures that  $AMF \leq 3$ ) can be found by using binary search along with the methods described in Section VII.

### IX. CONCLUSION

Motivated by applications in the area of network robustness and survivability, in this paper we focused on the problem of geographical network inhibition. Namely, we studied the properties and impact of geographical disasters that can be represented by either a line segment cut or a circular cut in the physical network graph. We considered a simple bipartite graph that abstracts the fiber links between the east and west coasts in the U.S. or trans-Atlantic/Pacific links. Then, we considered a general graph model in which nodes are located on the Euclidian

plane and studied two related problems in which cuts are modeled as line segments or as circular disks. For all cases, we developed polynomial-time algorithms for finding worst-case cuts. We then used the algorithms to obtain numerical results for various performance measures.

Our approach provides a fundamentally new way to look at network survivability under disasters or attacks that takes into account the geographical correlation between links. Some future research directions include the analytical consideration of arbitrarily shaped cuts and the use of computational geometric tools for the design of efficient algorithms. Moreover, we plan to study the impact of geographical failures on the design of survivable components, networks, and systems.

#### APPENDIX PROOF OF LEMMA 2

Let  $y_\omega(x) = (r_\omega - l_\omega)x + l_\omega$  be the equation of  $(i_\omega, j_\omega)$  on  $x \in [0, 1]$ . Let  $y_\alpha(x) = (r_\alpha - l_\alpha)x + l_\alpha$  be the equation of  $(i_\alpha, j_\alpha)$  on  $x \in [0, 1]$ . Let  $y_{ij}(x) = (r_j - l_i)x + l_i$  be the equation of  $(i, j)$  on  $x \in [0, 1]$ .

Consider the slopes of  $y_\omega(x)$  and  $y_\alpha(x)$ . There are two cases.

- 1) The slope of  $y_\omega(x)$  is smaller or equal to the slope of  $y_\alpha(x)$ :  

$$r_\omega - l_\omega \leq r_\alpha - l_\alpha.$$
- 2) The slope of  $y_\omega(x)$  is greater or equal to the slope of  $y_\alpha(x)$ :  

$$r_\omega - l_\omega \geq r_\alpha - l_\alpha.$$

We consider now the first case. Let

$$x' = \begin{cases} \min x, & \text{such that } x^* \leq x \leq 1 \text{ and} \\ & y_{ij}(x) = y_\alpha(x) \text{ for any } y_{ij} \text{ not } y_\alpha \text{ or} \\ & y_{ij}(x) = y_\omega(x) \text{ for any } y_{ij} \text{ not } y_\omega \\ 1, & \text{if the } x \text{ above does not exist.} \end{cases}$$

Essentially,  $x'$  is the first  $x$ -location after  $x^*$  where  $y_\omega(x)$  or  $y_\alpha(x)$  intersect another link. If  $y_\omega(x)$  or  $y_\alpha(x)$  do not intersect another link after  $x^*$ , then  $x' = 1$ .

We now show that  $x'$  is an  $x$ -location where it is possible to cut all the links that intersect  $\text{cut}_h(x^*, y^*)$ . Since links are line segments, we know  $y_{ij}(x') = y_{ij}(x^*) + (x' - x^*)(r_j - l_i) \forall i, j$ . Since we know  $y_\omega(x^*) \leq y_\alpha(x^*) + h$  [ $\text{cut}_h(x^*, y^*)$  intersects both  $y_\omega(x)$  and  $y_\alpha(x)$ ] and  $(r_\omega - l_\omega)(x' - x^*) \leq (r_\alpha - l_\alpha)(x' - x^*)$  (case 1 above and  $x' - x^* \geq 0$ ), we have  $y_\omega(x^*) + (r_\omega - l_\omega)(x' - x^*) \leq y_\alpha(x^*) + (r_\alpha - l_\alpha)(x' - x^*) + h$ . Thus,  $y_\omega(x') \leq y_\alpha(x') + h$ . See Fig. 9.

This means  $\text{cut}_h(x', y_\alpha(x'))$  will intersect both  $(i_\omega, j_\omega)$  and  $(i_\alpha, j_\alpha)$ . Since both these links do not intersect another link on  $x^* \leq x < x'$ , links that are intersected by  $\text{cut}_h(x^*, y^*)$  are also intersected by  $\text{cut}_h(x', y_\alpha(x'))$  (they are “trapped” between  $(i_\omega, j_\omega)$  and  $(i_\alpha, j_\alpha)$  on  $x^* \leq x < x'$ ).

Now we know  $\text{cut}_h(x', y_\alpha(x'))$  is a worst-case cut and  $x' = 1$ ,  $[x', y_\alpha(x')]$  is a link intersection, or  $[x', y_\omega(x')]$  is a link intersection. Therefore, by Lemma 1, we know there exists a worst-case cut that has an endpoint on a link intersection or node. The second case follows in an analogous fashion. ■

**Sebastian Neumayer** (M'10) received the B.S. degree (with Highest Honors) in electrical engineering from the University of Illinois at Urbana–Champaign in 2004, the M.S. degree in electrical engineering from the Massachusetts Institute of Technology (MIT), Cambridge, in 2007, and is currently pursuing the Ph.D. degree in electrical engineering at MIT.

Mr. Neumayer is a recipient of the NDSEG Fellowship.

**Gil Zussman** (S'02–M'05–SM'07) received the B.Sc. degree in industrial engineering and management and B.A. degree in economics (both *summa cum laude*) from the Technion—Israel Institute of Technology, Haifa, Israel, in 1995, the M.Sc. degree (*summa cum laude*) in operations research from Tel-Aviv University, Tel-Aviv, Israel, in 1999, and the Ph.D. degree in electrical engineering from the Technion in 2004.

Between 1995 and 1998, he served as an Engineer with the Israel Defense Forces. Between 2004 and 2007, he was a Post-Doctoral Associate with the Massachusetts Institute of Technology (MIT), Cambridge. He is currently an Assistant Professor with the Department of Electrical Engineering, Columbia University, New York, NY. His research interests are in the area of wireless networks.

Dr. Zussman received the Marie Curie Outgoing International Fellowship, the Fulbright Fellowship, the IFIP Networking 2002 Best Student Paper Award, and the OPNETWORK 2002 and ACM SIGMETRICS/IFIP Performance 2006 Best Paper Awards. He received the DTRA Young Investigator Award and the NSF CAREER Award, and was a member of a group that won first place in the 2009 Vodafone Foundation Wireless Innovation Project competition.

**Reuven Cohen** received the B.Sc. degree in physics and computer science and Ph.D. degree in physics from Bar-Ilan University, Ramat-Gan, Israel, in 1997 and 2004, respectively.

He was a Post-Doctoral Fellow with the Department of Mathematics and Computer Science, Weizmann Institute, Rehovot, Israel; the Electrical and Computer Engineering Department, Boston University, Boston, MA; and the Department of Physics, Massachusetts Institute of Technology (MIT), Cambridge. Since October 2007, he has been with the Department of Mathematics, Bar-Ilan University, where he is an Assistant Professor. His research interests are random graphs, distributed algorithms, and network stability.

**Eytan Modiano** (S'90–M'93–SM'00) received the B.S. degree in electrical engineering and computer science from the University of Connecticut, Storrs, in 1986, and the M.S. and Ph.D. degrees in electrical engineering, from the University of Maryland, College Park, in 1989 and 1992, respectively.

He was a Naval Research Laboratory Fellow between 1987 and 1992 and a National Research Council Post-Doctoral Fellow from 1992 to 1993. Between 1993 and 1999, he was with the Massachusetts Institute of Technology (MIT) Lincoln Laboratory, Cambridge, MA, where he was a project leader for MIT Lincoln Laboratory's Next Generation Internet (NGI) project. Since 1999, he has been with the faculty at MIT; where he is a Professor with the Department of Aeronautics and Astronautics and the Laboratory for Information and Decision Systems (LIDS). His research is on communication networks and protocols with emphasis on satellite, wireless, and optical networks.

Dr. Modiano is currently an Associate Editor for the IEEE/ACM TRANSACTIONS ON NETWORKING and had served as Associate Editor for the IEEE TRANSACTIONS ON INFORMATION THEORY. He was the Technical Program Co-Chair for IEEE WiOpt 2006, IEEE INFOCOM 2007, and ACM MobiHoc 2007. He is the co-recipient of the ACM SIGMETRICS 2006 Best Paper Award for the paper "Maximizing Throughput in Wireless Networks via Gossiping," and the WiOpt 2005 Best Student Paper Award for the paper "Minimum Energy Transmission Scheduling Subject to Deadline Constraints."
