Stochastic Regret Minimization in Extensive-Form Games

Gabriele Farina 1 Christian Kroer 2 Tuomas Sandholm 1 3 4 5

Abstract

Monte-Carlo counterfactual regret minimization (MCCFR) is the state-of-the-art algorithm for solving sequential games that are too large for full tree traversals. It works by using gradient estimates that can be computed via sampling. However, stochastic methods for sequential games have not been investigated extensively beyond MCCFR. In this paper we develop a new framework for developing stochastic regret minimization methods. This framework allows us to use any regret-minimization algorithm, coupled with any gradient estimator. The MCCFR algorithm can be analyzed as a special case of our framework, and this analysis leads to significantly stronger theoretical guarantees on convergence, while simultaneously yielding a simplified proof. Our framework allows us to instantiate several new stochastic methods for solving sequential games. We show extensive experiments on five games, where some variants of our methods outperform MCCFR.

1. Introduction

Extensive-form games (EFGs) are a broad class of games that can model sequential and simultaneous moves, outcome uncertainty, and imperfect information. This includes real-world settings such as negotiation, sequential auctions, security games (Lisý et al., 2016; Munoz de Cote et al., 2013), cybersecurity games (Debruhl et al., 2014; Chen et al., 2018), recreational games such as poker (Sandholm, 2010) and billiards (Archibald & Shoham, 2009), and medical treatment (Chen & Bowling, 2012; Sandholm, 2015).

Typically, EFG models are operationalized by computing either a Nash equilibrium of the game, or an approximate Nash equilibrium if the game is large. Approximate Nash equilibrium of zero-sum EFGs has been the underlying idea of several recent AI milestones, where strong AIs for two-player poker were created (Moravčík et al., 2017; Brown & Sandholm, 2017b). In principle, a zero-sum EFG can be solved in polynomial time using a linear program whose size is linear in the size of the game tree (von Stengel, 1996). However, for most real-world games this linear program is much too large to solve, either because it does not fit in memory, or because iterations of the simplex algorithm or interior-point methods become prohibitively expensive due to matrix inversion. Instead, first-order methods (Hoda et al., 2010; Kroer et al., 2020) or regret-based methods (Zinkevich et al., 2007; Tammelin et al., 2015; Brown & Sandholm, 2019a) are used in practice. These methods work by only keeping one or two strategies around for each player (typically the size of a strategy is much smaller than the size of the game tree). The game tree is then only accessed for computing gradients, which can be done via a single tree traversal (which can often be done without storing the tree), and sometimes game-specific structure can be exploited to speed this up further (Johanson et al., 2011). Finally, these gradients are used to update the strategy iterates.

However, for large games, even these gradient-based methods that require traversing the entire game tree are prohibitively expensive (henceforth referred to as deterministic methods). This was seen in two recent superhuman poker AIs: Libratus (Brown & Sandholm, 2017b) and Pluribus (Brown & Sandholm, 2019b). Both AIs were generated in a two-stage manner: an offline blueprint strategy was computed, and then refinements to the blueprint solution were computed online while actually playing against human opponents. The online solutions were computed using deterministic methods (since those subgames are significantly smaller than the entire game). However, the original blueprint strategies had to be computed without traversing the entire game tree, as this game tree is far too large for even a moderate amount of traversals.

When full tree traversals are too expensive, stochastic methods can be used to compute approximate gradients instead. The most common stochastic method for solving large EFGs is the Monte-Carlo Counterfactual Regret Minimization...
(MCCFR) algorithm \cite{Lanctot2009}. This algorithm, enhanced with certain dynamic pruning techniques, was also used to compute the blueprint strategies in the above-mentioned superhuman poker milestones \cite{Brown2015,Brown2017,Brown2019}. MCCFR combines the CFR algorithm \cite{Zinkevich2007} with certain stochastic gradient estimators. Follow-up papers have been written on MCCFR, investigating various methods for improving the sampling schemes used in estimating gradients and so on \cite{Gibson2012,Schmid2019}. However, beyond the MCCFR setting, stochastic methods have not been studied extensively for solving EFGs.

In this paper we develop a general framework for constructing stochastic regret-minimization methods for solving EFGs. In particular, we introduce a way to combine any regret-minimizing algorithm with any gradient estimator, and obtain high-probability bounds on the performance of the resulting combined algorithm. As a first application of our approach, we show that with probability $1 - p$, the regret in MCCFR is at most $O\left(\sqrt{\log(1/p)}\right)$ worse than that of CFR, an exponential improvement over the bound $O(\sqrt{1/p})$ previously known in the literature. Second, our approach enables us to de- 

2. Preliminaries

2.1. Two-Player Zero-Sum Extensive-Form Games

In this subsection we introduce the notation that we will use in the rest the paper when dealing with two-player zero-sum extensive-form games.

An extensive-form game is played on a tree rooted at a node $r$. Each node $v$ in the tree belongs to a player from the set $\{1, 2, c\}$, where $c$ is called the chance player. The chance player plays actions from a fixed distribution known to Player 1 and 2, and it is used as a device to model stochastic events such as drawing a random card from a deck. We denote the set of actions available at node $v$ by $A_v$. Each action corresponds to an outgoing edges from $v$. Given $a \in A_v$, we let $\rho(v, a)$ denote the node that is reached by following the edge corresponding to action $a$ at node $v$. Nodes $v$ such that $A_v = \emptyset$ are called leaves and represent terminal states of the game. We denote by $Z$ the set of leaves of the game. Associated with each leaf $z \in Z$ is a pair $(u_1(z), u_2(z)) \in \mathbb{R}^2$ of payoffs for Player 1 and 2, respectively. We denote by $\Delta$ the payoff range of the game, that is the value $\Delta := \max_{z \in Z} \max\{u_1(z), u_2(z)\} - \min_{z \in Z} \min\{u_1(z), u_2(z)\}$. In this paper we are concerned with zero-sum extensive-form games, that is games in which $u_1(z) = -u_2(z)$ for all $z \in Z$.

To model private information, the set of all nodes for each player $i \in \{1, 2, c\}$ is partitioned into a collection $\mathcal{I}_i$ of non-empty sets, called information sets. Each information set $I \in \mathcal{I}_i$ contains nodes that Player $i$ cannot distinguish among. In this paper, we will only consider perfect-recall games, that is, games in which no player forgets what he or she observed or knew earlier. Necessarily, if two nodes $u$ and $v$ belong to the same information set $I$, the set of actions $A_u$ and $A_v$ must be the same (or the player would be able to tell $u$ and $v$ apart). So, we denote by $A_I$ the set of actions of any node in $I$.

Sequences. The set of sequences for Player $i$, denoted $\Sigma_i$, is defined as the set of all possible information set-action pairs, plus a special element called empty sequence and denoted $\emptyset$. Formally, $\Sigma_i := \{(I, a) : I \in \mathcal{I}_i, a \in A_I \} \cup \{\emptyset\}$. Given a node $v$ for Player $i$, we denote with $\sigma_i(v)$ the last information set-action pair of Player $i$ encountered on the path from the root to node $v$; if the player does not act before $v$, $\sigma_i(I) = \emptyset$. It is known that in perfect-recall games $\sigma_i(u) = \sigma_i(v)$ for any two nodes $u, v$ in the same information set. For this reason, for each information set $I$ we define $\sigma_i(I)$ to equal $\sigma_i(v)$ for any $v \in I$.

Sequence-Form Strategies. A strategy for Player $i \in \{1, 2, c\}$ is an assignment of a probability distribution over the set of actions $A_I$ to each information set $I$ that belongs to Player $i$. In this paper, we represent strategies using their sequence-form representation \cite{Romanovskii1962,Koller1996,vonStengel1996}. A sequence-form strategy for Player $i$ is a non-negative vector $z$ indexed over the set of sequences $\Sigma_i$ of that player. For each $\sigma = (I, a) \in \Sigma_i$, the entry $z[\sigma]$ contains the product of the probability of all the actions that Player $i$ takes on the path from the root of the game tree down to action $a$ at information set $I$, included. In order for these probabilities to be consistent, it is necessary and sufficient that $z[\emptyset] = 1$ and

$$\sum_{a \in A_I} z[(I, a)] = z[\sigma_i(I)] \quad \forall I \in \mathcal{I}_i.$$ 

A strategy such that exactly one action is selected with probability $1$ at each node is called a pure strategy.
We denote by $\mathcal{X}$ and $\mathcal{Y}$ the set of all sequence-form strategies for Player 1 and Player 2, respectively. We denote by $e$ the fixed sequence-form strategy of the chance player.

For any leaf $z \in Z$, the probability that the game ends in $z$ is the product of the probabilities of all the actions on the path from the root to $z$. Because of the definition of sequence-form strategies, when Player 1 and 2 play according to strategies $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, respectively, this probability is equal to $x[\sigma_1(z)] \cdot y[\sigma_2(z)] \cdot e[\sigma_e(z)]$. So, Player 2’s expected utility is computed via the trilinear map

$$u_2(x, y, e) := \sum_{z \in Z} u_2(z) \cdot x[\sigma_1(z)] \cdot y[\sigma_2(z)] \cdot e[\sigma_e(z)].$$

(1)

Since the strategy of the chance player is fixed, the above expression is bilinear in $x$ and $y$ and therefore can be expressed more concisely as $u_2(x, y) = x^T A_2 y$, where $A_2$ is called the sequence-form payoff matrix of Player 2.

### 2.2. Regret Minimization

In this section we present the regret minimization algorithms that we will work with. We will operate within the framework of online convex optimization (Zinkevich [2003]). In this setting, a decision maker repeatedly makes decisions $z^1, z^2, \ldots$ from some convex compact set $Z \subseteq \mathbb{R}^n$. After each decision $z^t$ at time $t$, the decision maker faces a linear loss $\ell^t := (\ell^t)^T z^t$, where $\ell^t$ is a gradient vector in $\mathbb{R}^n$.

Given $\hat{z} \in Z$, the regret compared to $\hat{z}$ of the regret minimizer up to time $T$, denoted as $R^T(\hat{z})$, measures the difference between the loss cumulated by the sequence of output decisions $z^1, \ldots, z^T$ and the loss that would have been cumulated by playing a fixed, time-independent decision $\hat{z} \in Z$. In symbols, $R^T(\hat{z}) := \sum_{t=1}^T (\ell^t)^T (z^t - \hat{z})$. A “good” regret minimizer is such that the regret compared to any $\hat{z} \in Z$ grows sublinearly in $T$.

The two algorithms beyond MCCFR that we consider assume access to a distance-generating function $d : Z \rightarrow \mathbb{R}$, which is 1-strongly convex (with respect to some norm) and continuously differentiable on the interior of $Z$. Furthermore, $d$ should be such that the gradient of the convex conjugate $\nabla d(g) = \arg \max_{x \in Z} \langle g, z \rangle - d(z)$ is easy to compute. From $d$ we also construct the Bregman divergence $D(z \parallel z') := d(z) - d(z') - \langle \nabla d(z'), z - z' \rangle$.

We will use the following two classical regret minimization algorithms as examples that can be used in the framework that we introduce in this paper. The online mirror descent (OMD) algorithm produces iterates according to the rule

$$z^{t+1} = \arg \min_{z \in Z} \left\{ \left\langle \ell^t, z \right\rangle + \frac{1}{\eta} D(z \parallel z^t) \right\}.$$  

(2)

The follow the regularized leader (FTRL) algorithm produces iterates according to the rule (Shalev-Shwartz & Singer [2007])

$$z^{t+1} = \arg \min_{z \in Z} \left\{ \left\langle \ell^t, z \right\rangle + \frac{1}{\eta} D(z \parallel z^t) \right\}.$$  

(3)

OMD and FTRL satisfy regret bounds of the form $\max_{z \in Z} R^T(\hat{z}) \leq 2L \sqrt{D(z^* \parallel \hat{z})^2 / T}$, where $L$ is an upper bound on $\max_{x \in \mathbb{R}^n} \langle \ell^t \parallel x \rangle$ for all $t$. Here $\| \cdot \|$ is the norm with respect to which we measure strong convexity of $d$ (see, e.g., Orabona [2019]).

### 2.3. Equilibrium Finding in Extensive-Form Games using Regret Minimization

It is known that in a two-player extensive-form game, a Nash equilibrium (NE) is the solution to the bilinear saddle-point problem

$$\min_{x \in \mathcal{X}} \max_{y \in \mathcal{Y}} x^T A_2 y.$$

Given a pair $(x, y) \in \mathcal{X} \times \mathcal{Y}$ of sequence-form strategies for the Player 1 and 2, respectively, the saddle-point gap

$$\xi(x, y) := \max_{\tilde{y} \in \mathcal{Y}} \{ x^T A_2 \tilde{y} \} - \min_{\tilde{x} \in \mathcal{X}} \{ \tilde{x}^T A_2 y \}$$

measures of how far the pair is to being a Nash equilibrium. In particular, $(x, y)$ is a Nash equilibrium if and only if $\xi(x, y) = 0$.

Regret minimizers can be used to find a sequence of points $(x^t, y^t)$ whose saddle-point gap converges to 0. The fundamental idea is to instantiate two regret minimizers $R_1$ and $R_2$ for the sets $\mathcal{X}$ and $\mathcal{Y}$, respectively, and let them respond to each other in a self-play fashion using a particular choice of loss vectors (see Figure 1).

$$\xi(\bar{x}, \bar{y}) \leq (R_1^t + R_2^t) / T.$$  

(4)

Let $\bar{x}$ and $\bar{y}$ be the average of the strategies output by $R_1$ and $R_2$, respectively, up to time $T$. Furthermore, let $R_1^T := \max_{\bar{x} \in \mathcal{X}} R_1^T(\bar{x})$ and $R_2^T := \max_{\bar{y} \in \mathcal{Y}} R_2^T(\bar{y})$ be the maximum regret cumulated by $R_1$ and $R_2$ against any sequence-form strategy in $\mathcal{X}$ and $\mathcal{Y}$, respectively. A well-known folk lemma asserts that

$$\xi(\bar{x}, \bar{y}) \leq (R_1^T + R_2^T) / T.$$  

So, if $R_1$ and $R_2$ have regret that grows sublinearly, then the strategy profile $(\bar{x}, \bar{y})$ converges to a saddle point.

Figure 1. Self-play method for computing NE in EFGs.

At each time $t$, the strategies $x^t$ and $y^t$ output by the regret minimizers are used to compute the loss vectors

$$\ell_1^t := A_2 y^t, \quad \ell_2^t := -A_2^T x^t.$$  

(4)

Let $\bar{x}$ and $\bar{y}$ be the average of the strategies output by $R_1$ and $R_2$, respectively, up to time $T$. Furthermore, let $R_1^T := \max_{\bar{x} \in \mathcal{X}} R_1^T(\bar{x})$ and $R_2^T := \max_{\bar{y} \in \mathcal{Y}} R_2^T(\bar{y})$ be the maximum regret cumulated by $R_1$ and $R_2$ against any sequence-form strategy in $\mathcal{X}$ and $\mathcal{Y}$, respectively. A well-known folk lemma asserts that

$$\xi(\bar{x}, \bar{y}) \leq (R_1^T + R_2^T) / T.$$  

So, if $R_1$ and $R_2$ have regret that grows sublinearly, then the strategy profile $(\bar{x}, \bar{y})$ converges to a saddle point.
3. Stochastic Regret Minimization for Extensive-Form Games

In this section we provide some key analytical tools to understand the performance of regret minimization algorithms when gradient estimates are used instead of exact gradient vectors. The results in these sections are complemented by those of Section 4 where we introduce computationally cheap gradient estimators for the purposes of equilibrium finding in extensive-form games.

3.1. Regret Guarantees when Gradient Estimators are Used

We start by studying how much the guarantee on the regret degrades when gradient estimators are used instead of exact gradient vectors. Our analysis need not assume that we operate over extensive-form strategy spaces, so we present our results in full generality.

Let $\tilde{R}$ be a deterministic regret minimizer over a convex and compact set $Z$, and consider a second regret minimizer $R$ over the same set $Z$ that is implemented starting from $\tilde{R}$ as in Figure 2. In particular, at all times $t$,

- $R$ queries the next decision $z'$ of $\tilde{R}$, and outputs it;
- each gradient vector $\ell'$ received by $R$ is used by $\tilde{R}$ to compute a gradient estimate $\tilde{\ell}'$ such that $\mathbb{E}_t[\tilde{\ell}'] := \mathbb{E}[\ell' | \ell^1, \ldots, \ell^{t-1}] = \ell'$.

(that is, the estimate in unbiased). The internal regret minimizer $\tilde{R}$ is then shown $\tilde{\ell}'$ instead of $\ell'$.

Figure 2. Abstract regret minimizer considered in Section 3.1

The regret minimizer $R$ is a purely conceptual construction. We introduce $R$ in order to compare the regret incurred by $\mathcal{R}$ to that incurred by $\tilde{R}$. This will allow us to quantify the degradation in regret that is incurred when the gradient vectors are estimated instead of exact. In practice, it is not necessary to explicitly construct $\mathcal{R}$ and fully observe the gradient vectors $\ell'$ in order to compute the estimates $\tilde{\ell}'$. Examples of cheap gradient estimators for extensive-form games are given in Section 4.

When the estimate of the gradient is very accurate (for instance, it has low variance), it is reasonable to expect that the regret $R^T$ incurred by $\mathcal{R}$ up to any time $T$ is roughly equal to the regret $\tilde{R}^T$ that is incurred by $\tilde{R}$, plus some degradation term that depends on the error of the estimates. We can quantify this relationship by fixing an arbitrary $u \in Z$ and introducing the discrete-time stochastic process

$$d^t := (\ell^T)(z^t - u) - (\tilde{\ell}^T)(z^t - u).$$

Since by hypothesis $\mathbb{E}_t[\tilde{\ell}'] = \ell'$ and $\tilde{R}$ is a deterministic regret minimizer, $\mathbb{E}_t[d^t] = 0$ and so $\{d^t\}$ is a martingale difference sequence. This martingale difference sequence is well-known, especially in the context of bandit regret minimization (Abernethy & Rakhlin 2009; Bartlett et al. 2008). Using the Azuma-Hoeffding concentration inequality (Hoeffding 1963; Azuma 1967), we can prove the following.

**Proposition 1.** Let $M$ and $M$ be positive constants such that $|\langle \ell' \rangle(z - z')| \leq M$ and $|\langle \ell' \rangle(z - z')| \leq M$ for all times $t = 1, \ldots, T$ and all feasible points $z, z' \in Z$. Then, for all $p \in (0, 1)$ and all $u \in Z$,

$$\mathbb{P}\left[R^T(u) - \tilde{R}^T(u) + (M + M)\sqrt{2T \log \frac{1}{p}}\right] \geq 1 - p.$$  

A straightforward consequence of Proposition 1 is that if $\tilde{R}$ has regret that grows sublinearly in $T$, then also the regret of $R$ will grow sublinearly in $T$ with high probability.

**Remark.** As shown in Proposition 1, using gradient estimators instead of exact gradients incurs an additive regret degradation term that scales proportionally with the bound $M$ on the norm of the gradient estimates $\ell'$. We remark that the regret $\tilde{R}^T(u)$ also scales proportionally to the norm of the gradient estimates $\ell'$. So, increasing the value of $p$ in Proposition 1 is not enough to counter the dependence on $M$.

3.2. Connection to Equilibrium Finding

We now apply the general theory of Section 3.1 for the specific application of this paper—that is, Nash equilibrium computation in large extensive-form games.

We start from the construction of Section 2.3. In particular, we instantiate two deterministic regret minimizers $R_1, R_2$ and let them play strategies against each other. However, instead of computing the exact losses $\ell_1$ and $\ell_2$ as in (4), we compute their estimates $\tilde{\ell}_1$ and $\tilde{\ell}_2$ according to some algorithm that guarantees that $\mathbb{E}_t[\tilde{\ell}_1] = \ell_1$ and $\mathbb{E}_t[\tilde{\ell}_2] = \ell_2$ at all times $t$. We will show that despite this modification, the average strategy profile has a saddle point gap that is guaranteed to converge to zero with high probability.

Because of the particular definition of $\ell_1^t$, we have that at all times $t$,

$$\max_{x, x' \in X} \left|\langle \ell_1^t \rangle(x - x')\right| = \max_{x, x' \in X} \left|\langle x' \rangle A_{2}y - \langle x' \rangle A_{2}y\right| = \Delta,$$

where $\Delta$ is the payoff range of the game (see Section 2.1). (A symmetric statement holds for Player 2.) For $i \in \{1, 2\}$, let $M_i$ be positive constants such that $|\langle \ell_i^t \rangle(z - z')| \leq M_i$ at all times $t = 1, \ldots, T$ and all strategies $z, z'$ in the sequence-form polytope for Player $i$ (that is, $X$ when $i = 1$, and $Y$ when $i = 2$). Using Proposition 1, we find that for all $\hat{x} \in X$
and \( y \in \mathcal{Y} \), with probability (at least) \( 1 - p \),
\[
\sum_{t=1}^{T} (x^t - \bar{x})^\top A_2 y^t \leq \tilde{R}_1^2(\bar{x}) + (\Delta + \bar{M}_1) \sqrt{\frac{2T \log \frac{1}{p}}{p}}.
\]

where \( \tilde{R}_i \) denotes the regret of the regret minimizer \( \tilde{R}_i \) that at each time \( t \) observes \( \ell_i \).

Summing the above inequalities, dividing by \( T \), and using the union bound, we obtain that, with probability at least \( 1 - 2p \),
\[
\bar{x}^\top A_2 \bar{y} - x^\top A_2 y \leq \left( \frac{\tilde{R}_1^2(\bar{x}) + \tilde{R}_2^2(y)}{T} \right) + (2\Delta + \bar{M}_1 + \bar{M}_2) \sqrt{\frac{2}{T} \log \frac{1}{p}},
\]

where \( \bar{x} := \frac{1}{T} \sum_{t=1}^{T} x^t \) and \( \bar{y} := \frac{1}{T} \sum_{t=1}^{T} y^t \). Since \( \tilde{R}_1 \) holds for all \( x \in \mathcal{X} \) and \( y \in \mathcal{Y} \), we obtain the following.

**Proposition 2.** With probability at least \( 1 - 2p \),
\[
\xi(\bar{x}, \bar{y}) \leq \frac{\tilde{R}_1^2(\bar{x}) + \tilde{R}_2^2(y)}{T} + (2\Delta + \bar{M}_1 + \bar{M}_2) \sqrt{\frac{2}{T} \log \frac{1}{p}}.
\]

If \( \tilde{R}_1 \) and \( \tilde{R}_2 \) have regret that is sublinear in \( T \), then we conclude that the saddle point gap \( \xi(\bar{x}, \bar{y}) \) converges to 0 with high probability like in the non-stochastic setting. So, \( (\bar{x}, \bar{y}) \) converges to a saddle point over time.

### 4. Game-Theoretic Gradient Estimators

We complete the theory of Sections 3.1 and 3.2 by showing some examples of computationally cheap gradient estimators designed for game-theoretic applications. We will illustrate how each technique can be used to construct an estimate \( \bar{\ell}_i^t \) for the gradient \( \ell_i^t = A_2 y^t \) for Player 1 defined in (4). The computation of an estimate for \( \ell_2^t \) is analogous.

#### 4.1. External Sampling

An unbiased estimator of the gradient vector \( \ell_1^t = A_2 y^t \) can be easily constructed by independently sampling pure strategies \( y^t \) for Player 2 and \( c^t \) for the chance player. Indeed, as long as \( \mathbb{E}_i[y^t] = y^t \) and \( \mathbb{E}_i[c^t] = c^t \), from (4) we have that for all \( x \in \mathcal{X} \), \( y^t \sim \mathbb{E}_1[u_2(x, y^t, c)] \). Hence, the vector corresponding to the (random) linear function \( x \mapsto u_2(x, y^t, c^t) \) is an unbiased gradient estimator, called the external sampling gradient estimator.

Since at all times \( t \), \( y^t \) and \( c^t \) are sequence-form strategies, \( u_2(x, y^t, c^t) \) is lower bounded by the minimum payoff of the game and upper bounded by the maximum payoff of the game. Hence, for this estimator, \( M \) in Proposition 1 is equal to the payoff range \( \Delta \) of the game. Substituting that value into Proposition 2, we conclude that when the external sampling gradient estimator is used to estimate the gradient for both players, with probability at least \( 1 - 2p \) the saddle point gap of the average strategy profile \( (\bar{x}, \bar{y}) \) is
\[
\xi(\bar{x}, \bar{y}) \leq \frac{\tilde{R}_1^2(\bar{x}) + \tilde{R}_2^2(y)}{T} + 4\Delta \sqrt{\frac{2}{T} \log \frac{1}{p}}.
\]

The external sampling gradient estimator, that is, the vector corresponding to the linear function \( x \mapsto u_2(x, \bar{y}^{t}, \bar{c}^{t}) \), can be computed via a simple traversal of the game tree. The algorithm starts at the root of the game tree and starts visiting the tree. Every time a node that belongs to the chance player or to Player 2 is encountered, an action is sampled according to the strategy \( c \) or \( y^t \), respectively. Every time a node for Player 1 is encountered, the algorithm branches on all possible actions and recurses. A simple linear-time implementation is given as Algorithm 1. For every node of Player 2 or chance player, the algorithm branches on only one action. Thus computing an external sampling gradient estimate is significantly cheaper to compute than the exact gradient \( \ell_1^t \).

**Algorithm 1:** Efficient implementation of the external sampling gradient estimator

**Input:** \( y^t \) strategy for Player 2

**Output:** \( \bar{\ell}_1^t \) unbiased gradient estimate for \( \ell_1^t \) defined in (4)

1. \( \bar{\ell}_1^t \leftarrow 0 \in \mathbb{R}^{|\mathcal{X}|} \)

2. **subroutine** TraverseAndSample(\( v \))

3. \( I \leftarrow \text{info set to which } v \text{ belongs} \)

4. **if** \( v \) is a leaf **then**

5. \( \bar{\ell}_1^t[\sigma_1(v)] \leftarrow u_1(v) \)

6. **else if** \( v \) belongs to the chance player **then**

7. Sample an action \( a^* \sim \mathcal{E}_{\sigma_1(v)}[\sigma_2(v)] \) \( a \in A_v \)

8. TraverseAndSample(\( \rho(v, a^*) \))

9. **else if** \( v \) belongs to Player 2 **then**

10. Sample an action \( a^* \sim \mathcal{E}_{\sigma_1(v)}[\sigma_2(v)] \) \( a \in A_v \)

11. TraverseAndSample(\( \rho(v, a^*) \))

12. **else if** \( v \) belongs to Player 1 **then**

13. **for** \( a \in A_v \) **do**

14. TraverseAndSample(\( \rho(v, a) \))

15. TraverseAndSample(\( r \)) \( \triangleright r \) is root of the game tree

16. return \( \bar{\ell}_1^t \)

**Remark.** Analogous estimators where only the chance player’s strategy \( c \) or only Player 2’s strategy \( y^t \) are sampled are referred to as change sampling estimator and opponent sampling estimator, respectively. In both cases, the same value of \( M = \Delta \) (and therefore the bound in (7)) applies.

**Remark.** In the special case in which \( R_1 \) and \( R_2 \) run the CFR regret minimization algorithm, our analysis immediately implies the correctness of external-sampling MC-CFR, chance-sampling MCCFR, and opponent-sampling MCCFR, while at the same time yielding a significant improvement over the theoretical convergence rate to Nash
equilibrium of the overall algorithm: the right hand side of (7) grows as $\sqrt{\log(1/p)}$ in $p$, compared to the $O(1/p)$ of the original analysis by Lanctot et al. (2009).

Finally, we remark that our regret bound has a more favorable dependence on game-specific constants (for example, the number of information sets of each player) than the original analysis by Lanctot et al. (2009).

4.2. Outcome Sampling

Let $w^t \in X$ be an arbitrary strategy for Player 1. Furthermore, let $\tilde{z}^t \in Z$ be a random variable such that for all $z \in Z$,

$$P_t(\tilde{z}^t = z) = w^t(\sigma_1(z)) \cdot g^t(\sigma_2(z)) \cdot c[\sigma_2(z)]$$

and let $\tilde{e}_t$ be defined as the vector such that $c_2(\sigma_1(z)) = 1$ and $c_2[\sigma_2] = 0$ for all other $\sigma \in \Sigma_1, \sigma \neq \sigma_1(z)$. It is a simple exercise to prove that the random vector

$$\tilde{\ell}_t := \frac{w^t(\tilde{z}^t)}{w^t(\sigma_1(\tilde{z}^t))} \tilde{e}_t$$

is such that $E_t(\tilde{\ell}_t) = \ell^t$ (see Appendix A for a proof). This particular definition of $\tilde{\ell}_t$ is called the outcome sampling gradient estimator.

Computationally, the outcome sampling gradient estimator is cheaper than the external sampling gradient estimator. Indeed, since $w^t \in X$, one can sample $\tilde{z}^t$ by following a random path from the root of the game tree by sampling (from the appropriate player’s strategy) one action at each node encountered along the way. The walk terminates as soon as it reaches a leaf, which corresponds to $\tilde{z}$.

As we show in Appendix A, the value of $\tilde{M}$ for the outcome sampling gradient estimator is

$$\tilde{M} = \Delta \cdot \max_{\sigma \in \Sigma_1} \frac{1}{w^t(\sigma)}$$

So, the high-probability bound on the saddle point gap is inversely proportional to the minimum entry in $w^t$, as already noted by Lanctot et al. (2009).

4.2.1. Exploration-Balanced Outcome Sampling

In Appendix A we show that a strategy $w^*$ exists such that $w^*(\sigma) \geq 1/(|\Sigma| - 1)$ for every $\sigma \in \Sigma_1$. Since $w^*$ guarantees that all of the $|\Sigma_1|$ entries of $w^*$ are at least $1/(|\Sigma| - 1)$, we call $w^*$ the exploration-balanced strategy, and the corresponding outcome sampling regret estimator the exploration-balanced outcome sampling regret estimator. As a consequence of the above analysis, when both players’ gradients are estimated using the exploration-balanced outcome sampling regret estimator, with probability at least $1 - 2p$, the saddle point gap of the average strategy profile $\overline{(x, y)}$ is upper bounded as

$$\xi(\overline{x}, \overline{y}) \leq \frac{R^T_t(\overline{x}) + R^T_t(\overline{y})}{T} + 2(|\Sigma_1| + |\Sigma_2|)\Delta \sqrt{\frac{2}{T} \log \frac{1}{p}}.$$
We consider two variants of the game, which differ in the
with external sampling. We see that both FTRL and OMD

Goofspiel The variant of Goofspiel (Ross, 1971) that we use
in our experiments is a two-player card game,

Search is a security-inspired pursuit-evasion game. The
game is played on a graph shown in Figure 5 in Appendix B.

Leduc13. Leduc13 uses a deck of 13 unique cards, with two
copies of each card. The game has 166,336 nodes and 6,007
sequences per player.

Goofspiel The variant of Goofspiel (Ross, 1971) that we use
in our experiments is a two-player card game, employing
three identical decks of 4 cards each. This game has 54,421
nodes and 21,329 sequences per player.

Search is a security-inspired pursuit-evasion game. The
game is played on a graph shown in Figure 5 in Appendix B.

Battleship is a parametric version of a classic board game,
where two competing fleets take turns shooting at each
other (Farina et al., 2019c). The game has 732,607 nodes,
73,130 sequences for Player 1, and 253,940 sequences for
Player 2.

5.1. External Sampling

Figure 3 (top left) shows the performance on Battleship
with external sampling. We see that both FTRL and OMD
perform better than MCCFR when using stepsize $\eta = 10$. In
Goofspiel (top right plot) we find that OMD performs
significantly worse than MCCFR and FTRL. MCCFR performs
slightly better than FTRL also. In Leduc 13 (bottom left) we find that OMD performs significantly worse than
MCCFR and FTRL. FTRL performs slightly better than
MCCFR. Finally, in Search-4 (bottom right) we find that
OMD and MCCFR perform comparably, while FTRL per-
forms significantly better. Due to space limitations, we show
the experimental evaluation for Search-5 in Appendix C. In
Search-5 all algorithms perform comparably, with FTRL
performing slightly better than OMD and MCCFR.

Summarizing across all five games for external sampling,
we see that FTRL, either with $\eta = 10$ or $\eta = 100$, was better
than MCCFR on four out of five games (and essentially tied
on the last game), with significantly better performance in
the Search games. OMD performs significantly better then
MCCFR and FTRL. FTRL performs slightly better than
MCCFR.

5.2. Exploration-Balanced Outcome Sampling

Next, we investigate the performance of our exploration-
balanced outcome sampling. For that gradient estimator we
drew 100 outcome samples per gradient estimate, and use
the empirical mean of those 100 samples as our estimate.
The reason for this is that FTRL and OMD seem more
sensitive to stepsize issues under outcome sampling. It can
be shown easily that by averaging gradient estimators, the
constant $M$ required in Proposition 1 does not increase.
Due to computational time issues, we present performance for only 10 random seeds per game in outcome sampling. For this reason we omit performance on Search-4, which seemed too noisy to make conclusions about. Search-4 plots can be found in Appendix C.

Figure 4 (top left) shows the performance on Battleship with outcome sampling. Here all algorithms perform essentially identically, with MCCFR performing significantly worse for a while, then slightly better, and then they all become similar around $3 \times 10^7$ nodes touched.

In Goofspiel (top right), MCCFR performs significantly better than both FTRL and OMD. Both FTRL and OMD were best with $\eta = 100$, our largest stepsize. It thus seems likely that even more aggressive stepsizes are needed in order to get better performance in Goofspiel.

In Leduc13 (bottom left), FTRL with outcome sampling is initially slower than MCCFR, but eventually overtakes it. OMD is significantly worse than the other algorithms.

Finally, in Search-5 (bottom right), MCCFR performs significantly better than FTRL and OMD, although FTRL seems to be catching up in later iterations.

Overall, when the exploration-balanced outcome sampling gradient estimator is used for all three algorithms, MCCFR seems to perform better than FTRL and OMD. In two out of four games it is significantly better, in one it is marginally better, and in one FTRL is marginally better. We hypothesize that FTRL and OMD are much more sensitive to stepsize issues with outcome sampling as opposed to external sampling. This would make sense, as the variance becomes much higher.

6. Conclusion

We introduced a new framework for constructing stochastic regret-minimization methods for solving zero-sum games. This framework completely decouples the choice of regret minimizer and gradient estimator, thus allowing any regret minimizer to be coupled with any gradient estimator. Our framework also yields a streamlined and dramatically simpler proof of MCCFR. Furthermore, it immediately gives a significantly stronger bound on the convergence rate of MCCFR, whereby with probability $1 - p$ the regret grows as $O(\sqrt{T \log(1/p)})$ instead of $O(\sqrt{T/p})$ as in the original analysis—an exponentially better bound. We also instantiated stochastic variants of the FTRL and OMD algorithms for solving zero-sum EFGs using our framework. Extensive numerical experiments showed that it is often possible to beat MCCFR using these algorithms, even with a very mild amount of stepsize tuning. Due to its modular nature, our framework opens the door to many possible future research questions around stochastic methods for solving EFGs. Among the most promising are methods for controlling the stepsize in, for instance, FTRL or OMD, as well as instantiating our framework with other regret minimizers.
One potential avenue for future work is to develop gradient-estimation techniques with stronger control over the variance. In that case, it is possible to derive a variation of Proposition \ref{prop:main} that is based on the sum of conditional variances, an intrinsic notion of time in martingales (e.g., \cite{Blackwell1967}). In particular, using the Freedman-style (\cite{Freedman1975}) concentration result of \cite{Bartlett2008} for martingale difference sequences, we obtain:

**Proposition 3.** Let \( T \geq 4 \), and let \( M \) and \( \tilde{M} \) be positive constants such that \( |(\mathcal{E}^T)(z-u)| \leq M \) and \( |(\mathcal{E}^T)(z-u)| \leq \tilde{M} \) for all times \( t = 1, \ldots, T \) and all feasible points \( z,u \in \mathcal{X} \). Furthermore, let \( \sigma := \sqrt{\sum_{t=1}^T \text{Var}[d_t | \hat{\ell}_1, \ldots, \hat{\ell}_{t-1}]} \) be the square root of the sum of conditional variances of the random variables \( d_t \) introduced in \cite{Bartlett2008}. Then, for all \( p \in (0, 1/2] \) and all \( u \in \mathcal{X} \),

\[
P\left[ R_T^T(u) \leq \tilde{R}_T^T(u) + 4 \max \{ \sigma \beta, (M + \tilde{M}) \beta^3 \} \right] \geq 1 - p,
\]

where \( \beta := \sqrt{\log \left( \frac{\log T}{p} \right)} \).

The concentration result of Proposition 3 takes into account the variance of the martingale difference sequences. When the variance is low, the dominant term in the right hand side of the inequality is \( (M + \tilde{M}) \beta^2 = \mathcal{O}(\log \log T) \). On the other hand, when the variance is high (that is, \( \sigma \) grows as \( \sqrt{T} \)), we recover a bound similar to the Azuma-Hoeffding inequality (albeit with a slightly worse polylog dependence on \( T \)).

Finally, our framework can also be applied to more general EFG-like problems, and thus this work also enables one to instantiate MCCFR or other stochastic methods for new sequential decision-making problems, for example by using the generalizations of CFR in \cite{Farina2019a} or \cite{Farina2019b}.

Stochastic Regret Minimization in Extensive-Form Games

A. Proofs

A.1. Regret Guarantees when Gradient Estimators are Used

For completeness, we show a proof of Proposition 1. As mentioned, it is an application of the Azuma-Hoeffding inequality for martingale difference sequences, which we now state (see, e.g., Theorem 3.14 of McDiarmid (1998) for a proof).

**Theorem 1** (Azuma-Hoeffding inequality). Let \( Y_1, \ldots, Y_n \) be a martingale difference sequence with \( a_k \leq Y_k \leq b_k \) for each \( k \), for suitable constants \( a_k, b_k \). Then for any \( \tau \geq 0 \),

\[
P\left[ \sum_{k=1}^{n} Y_k \geq \tau \right] \leq e^{-2\tau^2/\sum(b_k-a_k)^2}.
\]

**Proposition 1.** Let \( M \) and \( \tilde{M} \) be positive constants such that \( |(\ell_t)\top (z - z')| \leq M \) and \( |(\tilde{\ell})\top (z - z')| \leq \tilde{M} \) for all times \( t = 1, \ldots, T \) and all feasible points \( z, z' \in \mathbb{Z} \). Then, for all \( p \in (0, 1) \) and all \( u \in \mathbb{Z} \),

\[
P\left[ R_T^T(u) \leq \tilde{R}_T^T(u) + (M + \tilde{M}) 2T \log \frac{1}{p} \right] \geq 1 - p.
\]

**Proof.** As observed in the body, \( d_t := (\ell_t)\top (z^t - u) - (\tilde{\ell}_t)\top (z^t - u) \) is a martingale difference sequence. Furthermore, at all times \( t \),

\[
|d_t| = |(\ell_t)\top (z^t - u) - (\tilde{\ell}_t)\top (z^t - u)| \\
\leq |(\ell_t)\top (z^t - u)| + |(\tilde{\ell}_t)\top (z^t - u)| \\
\leq M + \tilde{M},
\]

and therefore \( -(M + \tilde{M}) \leq d_t \leq (M + \tilde{M}) \) for each \( t \).

Furthermore,

\[
\sum_{t=1}^{T} d_t = \left( \sum_{t=1}^{T} (\ell_t)\top (z^t - u) \right) - \left( \sum_{t=1}^{T} (\tilde{\ell}_t)\top (z^t - u) \right) = R_T^T(u) - \tilde{R}_T^T(u).
\]

So, using Theorem 1 for all \( \tau \geq 0 \)

\[
P\left[ R_T^T(u) \leq \tilde{R}_T^T(u) + \tau \right] = P\left[ \sum_{t=1}^{T} d_t \leq \tau \right] \\
= 1 - P\left[ \sum_{t=1}^{T} d_t \geq \tau \right] \\
\geq 1 - \exp\left\{ -\frac{2\tau^2}{\sum_{t=1}^{T} 4(M + \tilde{M})^2} \right\} \\
= 1 - \exp\left\{ -\frac{2\tau^2}{4T(M + \tilde{M})^2} \right\}.
\]

Finally, substituting \( \tau = (M + \tilde{M}) \sqrt{2T \log(1/p)} \) yields the statement.

A.2. Properties of the Outcome Sampling Gradient Estimator

Let \( w^t \in X \) be an arbitrary strategy for Player 1. Furthermore, let \( z^t \in Z \) be a random variable such that for all \( z \in Z \),

\[
P(z^t = z) = w^t[\sigma_1(z)] \cdot y^t[\sigma_2(z)] \cdot c[\sigma(c(z))],
\]

and let \( e_z \) be defined as the vector such that \( e_z[\sigma_1(z)] = 1 \) and \( e_z[\sigma] = 0 \) for all other \( \sigma \in \Sigma_1, \sigma \neq \sigma_1(z) \).

**Lemma 1.** The random vector

\[
\tilde{\ell}_t^t := \frac{u_2(z^t)}{w^t[\sigma_1(z^t)]} e_z
\]

is such that \( \mathbb{E}[\tilde{\ell}_t^t] = \ell_t^t \).
We now describe the construction of the exploration-balanced strategy for all $\sigma \in \Sigma_1$. Let $\tilde{E}_t[\ell_1^t] = \sum_{z \in Z} \mathbb{P}[z^t = z] \cdot \frac{u_1(z)}{w^t[\sigma_1(z)]} e_z$.

For all $x \in \mathbb{R}^{[\Sigma_1]}$,

$$E_t[\ell_1^t] \mathsf{x} = \left( \sum_{z \in Z} \mathbb{P}[z^t = z] \cdot \frac{u_1(z)}{w^t[\sigma_1(z)]} e_z \right) \mathsf{x}$$

$$= \left( \sum_{z \in Z} u_2(z) \cdot y^t[\sigma_2(z)] \cdot c[\sigma_1(z)] \cdot e_z \right) \mathsf{x}$$

$$= \sum_{z \in Z} u_2(z) \cdot y^t[\sigma_2(z)] \cdot c[\sigma_1(z)] \cdot c[\sigma_1(z)] \cdot (e_z^T \mathsf{x})$$

$$= \sum_{z \in Z} u_2(z) \cdot y^t[\sigma_2(z)] \cdot c[\sigma_1(z)] \cdot x[\sigma_1(z)]$$

$$= u_2(x, y^t, c) = \ell_1^T \mathsf{x}.$$ 

Since the equality holds for all $x \in \mathbb{R}^{[\Sigma_1]}$, we conclude $E_t[\ell_1^t] = \ell_1$. $\square$

Furthermore, Lemma 2. For all $x, x' \in X$,

$$(\ell_1^T (x - x')) \leq \Delta \cdot \max_{\sigma \in \Sigma_1} \frac{1}{w^T[\sigma]}.$$ 

Proof. Using the definition of $\ell_1$,

$$(\ell_1^T (x - x')) = \frac{u_2(z)}{w^t[\sigma_1(z^t)]} \left( x[\sigma_1(z^t)] - x'[\sigma_1(z^t)] \right).$$

Since each entry of $x$ and $x'$ is in the interval $[0, 1]$, the quantity $x[\sigma_1(z^t)] - x'[\sigma_1(z^t)]$ has absolute value in $[0, 1]$ as well. Hence,

$$|(\ell_1^T (x - x'))| \leq \max_{z \in Z} \left| \frac{u_2(z)}{w^t[\sigma_1(z^t)]} \right| \leq \Delta \cdot \max_{\sigma \in \Sigma_1} \frac{1}{w^T[\sigma]}$$

as we wanted to show. $\square$

### A.3. Exploration-Balanced Strategy

We now describe the construction of the exploration-balanced strategy $w^\star$. Given $\sigma \in \Sigma_1$, we let $C_\sigma$ be the set of information sets $I(\mathcal{I})$ such that $\sigma(I) = \sigma$. Furthermore, let $m_\sigma$, for $\sigma \in \Sigma_1$, be the number of terminal sequences in the subtree rooted under $\sigma$; formally, $m_\sigma$ is defined recursively as

$$m_\sigma = \begin{cases} 1 & \text{if } C_\sigma = \emptyset; \\ \sum_{I \in C_\sigma} \sum_{a \in A_I} m_{I(a)} & \text{otherwise.} \end{cases}$$

Clearly, $m_\sigma \leq |\Sigma_1| - 1$, since the empty sequence is never terminal (assuming Player 1 acts at least once). With that, we define $w^\star$ such that $w^\star[\emptyset] = 1$ and that for all $\sigma = (I, a) \in \Sigma_1$,

$$w^\star[\sigma] = \frac{m_\sigma}{\sum_{a' \in A_I} m_{I(a')}} w^\star[\sigma_1(I)].$$

It is immediate to verify that $w^\star$ is indeed a valid sequence-form strategy. Furthermore, since for all $I \in \mathcal{I}_I, I \in C_{\sigma_1(I)}$, we have

$$\sum_{a' \in A_I} m_{I(a')} \leq m_{\sigma(I)}.$$ 

So,

$$w^\star[\sigma] \geq \frac{m_\sigma}{m_{\sigma_1(I)}} w^\star[\sigma_1(I)].$$ 

By recursively expanding the definition of $w^\star[\sigma_1(I)]$ on the right-hand side until $\sigma_1(I) = \emptyset$, we ultimately obtain

$$w^\star[\sigma] \geq \frac{1}{m_\emptyset} \geq \frac{1}{|\Sigma_1| - 1}$$

for all $\sigma$, as we wanted to show.
A.4. Proposition 3

As mentioned in the body of the paper, Proposition 3 is a direct consequence of the concentration result for martingale difference sequences of Bartlett et al. (2008), which we state next.

**Lemma 3** (Lemma 2 of Bartlett et al. (2008)). Suppose $X^1, \ldots, X^T$ is a martingale difference sequence with $|X^t| \leq b$. Let $\Var_t X^t := \Var[X^t \mid X^1, \ldots, X^{t-1}]$.

Let $V := \sum_{t=1}^T \Var_t X^t$ be the sum of conditional variances of $X^t$'s. Further, let $\sigma := \sqrt{V}$. Then we have, for any $\delta < 1/e$ and $T \geq 4$,

$$\Pr\left[ \sum_{t=1}^T X^t > 2 \max\{2\sigma, b\sqrt{\log(1/\delta)}\}\sqrt{\log(1/\delta)} \right] \leq \log(T)\delta.$$ 

**Proposition 3.** Let $T \geq 4$, and let $M$ and $\tilde{M}$ be positive constants such that $|\langle\ell^t\rangle^T (z - u)| \leq M$ and $|\langle\ell^t\rangle^T (z - u)| \leq \tilde{M}$ for all times $t = 1, \ldots, T$ and all feasible points $z, u \in X$. Furthermore, let $\sigma := \sqrt{\sum_{t=1}^T \Var[\ell^t \mid \ell^1, \ldots, \ell^{t-1}]}$, be the square root of the sum of conditional variances of the random variables $\ell^t$ introduced in [5]. Then, for all $p \in (0, 1/2]$ and all $u \in X$,

$$\Pr\left[ R^T(u) \leq R^T(u) + 4 \max\{\sigma\beta, (M + \tilde{M})\beta^2\} \right] \geq 1 - p,$$

where

$$\beta := \sqrt{\log\left(\frac{\log T}{p}\right)}.$$

**Proof.** We apply Lemma 3 to the martingale difference sequence $X^t = d_t$. As argued in [8], $|X^t| \leq (M + \tilde{M})$ at all times $t$, so the constant $b = M + \tilde{M}$ satisfies the requirements of Lemma 3. Finally, we set $\delta = p/\log(T)$ in Lemma 3 so that

$$\sqrt{\log(1/\delta)} = \sqrt{\log\left(\frac{\log T}{p}\right)} = \beta.$$

Furthermore, since by hypothesis $T \geq 4$ and $p \leq 1/2$, $\delta = p/\log(T) \leq 1/(2\log 4) \leq 1/e$, so all hypotheses of Lemma 3 are satisfied. Hence, we have

$$\Pr\left[ R^T(u) - R^T(u) \leq 4 \max\{\sigma\beta, (M + \tilde{M})\beta^2\} \right] = \Pr\left[ \sum_{t=1}^T X^t \leq 4 \max\{\sigma\beta, b\beta^2\} \right]$$

$$= \Pr\left[ \sum_{t=1}^T X^t \leq 4 \max\{\sigma\sqrt{\log(1/\delta)}, b\log(1/\delta)\} \right]$$

$$= \Pr\left[ \sum_{t=1}^T X^t \leq 2 \max\{2\sigma, 2b\sqrt{\log(1/\delta)}\}\sqrt{\log(1/\delta)} \right]$$

$$\geq \Pr\left[ \sum_{t=1}^T X^t \leq 2 \max\{2\sigma, b\sqrt{\log(1/\delta)}\}\sqrt{\log(1/\delta)} \right]$$

$$\geq 1 - \log(T)\delta = 1 - p,$$

where the last inequality follows from Lemma 3.

B. Description of the Game Instances Used in the Experiments

We run our experiments on four different games, each described below.

**Leduc poker** is a standard benchmark in the EFG-solving community (Southey et al., 2005). Our variant, Leduc 13, has a deck of 13 unique cards, with two copies of each card. The game consists of two rounds. In the first round, each player places an ante of 1 in the pot and receives a single private card. A round of betting then takes place with a two-bet maximum, with Player 1 going first. A public shared card is then dealt face up and another round of betting takes place. Again, Player 1 goes first, and there is a two-bet maximum. If one of the players has a pair with the public card, that player wins. Otherwise, the player with the higher card wins. All bets in the first round are 1, while all bets in the second round are 2. This game has 166336 nodes and 6007 sequences per player.
Goofspiel The variant of Goofspiel (Ross [1971]) that we use in our experiments is a two-player card game, employing three identical decks of 4 cards each. At the beginning of the game, each player receives one of the decks to use it as its own hand, while the last deck is put face down between the players, with cards in increasing order of rank from top to bottom. Cards from this deck will be the prizes of the game. In each round, the players privately select a card from their hand as a bet to win the topmost card in the prize deck. The selected cards are simultaneously revealed, and the highest one wins the prize card. In case of a tie, the prize card is discarded. Each prize card’s value is equal to its face value, and at the end of the game the players’ score are computed as the sum of the values of the prize cards they have won. This game has 54421 nodes and 21329 sequences per player.

Search is a security-inspired pursuit-evasion game. The game is played on the graph shown in Figure 5.

It is a simultaneous-move game (which can be modeled as a turn-taking EFG with appropriately chosen information sets). The defender controls two patrols that can each move within their respective shaded areas (labeled P1 and P2). At each time step the controller chooses a move for both patrols. The attacker is always at a single node on the graph, initially the leftmost node labeled S. The attacker can move freely to any adjacent node (except at patrolled nodes, the attacker cannot move from a patrolled node to another patrolled node). The attacker can also choose to wait in place for a time step in order to clean up their traces. If a patrol visits a node that was previously visited by the attacker, and the attacker did not wait to clean up their traces, they can see that the attacker was there. If the attacker reaches any of the rightmost nodes they receive the respective payoff at the node (5, 10, or 3, respectively). If the attacker and any patrol are on the same node at any time step, the attacker is captured, which leads to a payoff of −1 for the attacker and a payoff of 1 for the defender. Finally, the game times out after k simultaneous moves, in which case both players defender receive payoffs 0. Search-4 (Search-5) has 21613 (87,927) nodes, 2029 (11,830) defender sequences, and 52 (69) attacker sequences.

Our search game is a zero-sum variant of the one used by Kroer et al. (2018). A similar search game considered by Bošanský et al. (2014) and Bošanský & Čermák (2015).

Battleship is a parametric version of a classic board game, where two competing fleets take turns shooting at each other (Farina et al., 2019c). At the beginning of the game, the players take turns at secretly placing a set of ships on separate grids (one for each player) of size 3 × 2. Each ship has size 2 (measured in terms of contiguous grid cells) and a value of 1, and must be placed so that all the cells that make up the ship are fully contained within each player’s grids and do not overlap with any other ship that the player has already positioned on the grid. After all ships have been placed, the players take turns at firing at their opponent. Ships that have been hit at all their cells are considered sunk. The game continues until either one player has sunk all of the opponent’s ships, or each player has completed r shots. At the end of the game, each player’s payoff is calculated as the sum of the values of the opponent’s ships that were sunk, minus the sum of the values of ships which that player has lost. The game has 732607 nodes, 73130 sequences for player 1, and 253940 sequences for player 2.

C. Additional Experimental Results

C.1. External Sampling

The Search-5 plot omitted from the main paper is shown here.
Figure 6. Performance of MCCFR, FTRL, and OMD with external sampling on Search-5.

Figures 7 through 11 show the performance of FTRL and OMD for all four stepsizes that we tried on each game: $\eta = 0.1, 1, 10, 100$.

Figure 7. Performance of FTRL and OMD with four stepsizes on Battleship with external sampling. MCCFR shown for reference

Figure 8. Performance of FTRL and OMD with four stepsizes on Goofspiel with external sampling. MCCFR shown for reference
C.2. Exploration-Balanced Outcome Sampling

The Search-4 plot omitted from the main paper is shown here.
Figure 12. Performance of MCCFR, FTRL, and OMD with outcome sampling on Search-4.

Figure 12 shows the performance on Search-4 and Search-5 with outcome sampling. In Search-4 we find that MCCFR performs better than FTRL and OMD, though FTRL is comparable at later iterations.

Figures 13 through 17 show the performance of FTRL and OMD with outcome sampling for all four stepsizes that we tried on each game: \( \eta = 0.1, 1, 10, 100 \).
