Rare Disasters and Risk Sharing with Heterogeneous Beliefs

Hui Chen Scott Joslin Ngoc-Khanh Tran*

January 31, 2010

Abstract

Although the threat of rare economic disasters can have large effect on asset prices, difficulty in inference regarding both their likelihood and severity provides the potential for disagreements among investors. Such disagreements lead investors to insure each other against the types of disasters each one fears most. Due to the highly non-linear relationship between consumption losses in a disaster and the risk premium, a small amount of risk sharing can significantly attenuate the effect that disaster risk has on the equity premium. The impact of risk sharing becomes stronger when the differences in beliefs get larger or when the minority wealth holders in the economy have lower risk aversion. Our model implies a non-monotonic relationship between the equity premium and the size of the disaster insurance market. It also shows that the equity premium can sometimes become lower as market participants on average become more concerned with disaster risk.

1 Introduction

In this paper, we demonstrate how heterogeneous beliefs about rare disasters affect asset prices and trading activities. Research by Rietz (1988), Longstaff and Piazzesi (2004), Barro (2006) and others show that the threat of rare economic disasters that cause severe losses in output and consumption can have large impact on the equity premium. However, with a relatively short sample of historical data, it is difficult to estimate the likelihood of disasters or the size of their impact, which suggests that there is likely to be large heterogeneity in the beliefs of market participants about disasters. We show that such disagreements can generate strong risk sharing motives among investors and significantly affect asset prices in the equilibrium.

We study an exchange economy with two types of agents, whose beliefs on disasters can differ in various ways. For example, one type of agents can be more optimistic about disaster risk than the other. These optimists might believe in a lower probability of disasters (e.g., once every 1000 years as opposed to once every 60 years), or they might think the potential loss of aggregate endowment during a disaster is smaller. Alternatively, both types of agents could be concerned about disasters, except that one thinks disasters are large and rare, while the other thinks they are smaller but more frequent. We assume that markets are complete, so that the agents can trade contingent claims and achieve optimal risk sharing. Thus, equilibrium asset prices depend on the beliefs and the distribution of wealth among the agents.

Our main finding is that adding a second type of agents with different beliefs about disasters can cause the equity premium to drop substantially, even when the new agents only have a small amount of wealth. This result holds whether the disagreement is about the intensity or impact of disasters. Interestingly, this result is still true even when the new agents are generally more pessimistic about disasters, so long as they believe the disasters the original agents fear most are relatively less likely. When we calibrate the beliefs of one agent using international data (from Barro (2006)), the other using only consumption data from the US (where disasters have been relatively mild), raising the fraction of total wealth for the second agent from 0 to 10% lowers the equity premium from 4.4% to 2.0%. The decline in the equity premium becomes faster when the disagreement is larger, or when the new agents also have lower risk aversion.

[1] In the sense that the distribution of consumption growth under one’s beliefs first-order stochastically dominates that of the other’s.
The key reasons behind this result are the following: (1) the equity premium derives almost entirely from jump (disaster) risk, (2) high prices for jump risk induce aggressive risk sharing, and (3) there is a highly nonlinear relationship between risk premium and disaster risk.

First, in our economy, as is typically the case in standard power utility models, there is very little compensation for Brownian risk due to the low volatility of consumption and moderate levels of risk aversion. Consequently, the equity premium derives primarily from disaster risk, and the compensation for bearing disaster risk must be high. For example, if there is a single type of disaster resulting in a 40% loss to the consumption claim and the equity premium due to disaster risk is 4%, then the annual premium for a disaster insurance contract that pays $1 when disaster strikes must cost 10 cents or more, regardless of the actual chance of payoff.

Second, the high premium for disaster risk provides a strong motivation for risk sharing when agents have different beliefs about disasters. In a benchmark example of our model, the pessimists may be willing to pay up to 13 cents per $1 of insurance coverage, even though the payoff probability is only 1.7% under their own beliefs, or 0.1% under the beliefs of the optimistic agents. Such high prices induce the optimists to underwrite insurance contracts with notional value up to 40% of their total wealth, despite the risk of losing 70% of their consumption if a disaster strikes.

Third, the disaster risk premium is highly non-linear in the size of disasters, so that small amounts of risk sharing may have significant effects on risk premia. Since disasters are rare, in order for them to have large impact on the risk premium, marginal utility in the disaster states needs to rise substantially as the size of the consumption drop increases. With power utility, this is achieved by having marginal utility rise with the log disaster size at an exponential rate. As a result, the equity premium is sensitive to changes in the size of individual consumption losses during a disaster. For example, if an agent (with $\gamma = 4$) manages to reduce her consumption loss in a disaster from 40% to 35%, the equity premium she demands will fall by 40%! Thus, a small amount of risk sharing between agents with heterogeneous beliefs is enough to significantly lower the equity premium they demand.

It is important to point out that the above mechanism does not require the new agents to be “globally” more optimistic about disasters than the existing ones. The critical component in the risk sharing mechanism is the existence of minority investors who believe that the types of disasters the majority wealth holders fear most are relatively less likely to occur. Although these minority
investors may fear other disasters (perhaps even larger and/or more frequent ones), they will still be willing to share the disaster risk the majority wealth holders fear. Thus, heterogeneity among agents may result in a low equity premium even if each would individually demand a high equity premium when other types of agents are not present.

Our model implies that the market risk premium can still remain low when the majority of market participants are concerned with the risks of major disasters. Before a disaster strikes, the optimistic investors gain wealth by selling disaster insurance, which gradually drives down the equity premium. This occurs regardless of the true likelihood of disasters; that is, agents with correct pessimistic beliefs about disasters will lose wealth to agents with incorrect beliefs in times outside of disasters. However, when a disaster occurs, these optimists will lose a large fraction of their wealth, and their risk sharing capacity will be greatly reduced. As a result, the equity premium will jump up significantly.

A number of other interesting results and predictions arise from our analysis. First, we show that historical data combined with simple economic restrictions can provide useful bounds on beliefs about disasters. While sampling error puts tight restrictions on the mean of consumption growth, it leaves much more room for disagreements about the frequency of disasters. Second, we show that the degree to which variation in the disaster intensity influences asset prices and risk premia crucially depends on the distribution of wealth among agents with different beliefs. Moreover, although the wealth distribution in our model is non-stationary, agents who are overly optimistic about disasters are likely to survive and even gain wealth for long periods of time. Third, our model predicts that the equity premium is not necessarily increasing in investors’ weighted average belief of disaster risk; the premium could become lower if the rise in the average perceived disaster risk is accompanied by larger disagreements. Finally, similar to the link between asset prices and the size of the market for riskless lending in Longstaff and Wang (2008), our model predicts a non-monotonic relationship between the equity premium and the size of the disaster insurance market.

This paper contributes to the disaster risk literature, which goes back to the work of Rietz (1988). Barro (2006, 2009) has reinvigorated this literature by providing international evidence that disasters have been frequent and severe enough to generate a large equity premium. A series of recent studies demonstrate that disaster risk can also help match a wide range of facts in
financial markets, including asset volatility, return predictability, corporate bond spreads, option pricing, exchange rates, etc. Among these studies are Liu, Pan, and Wang (2005), Gabaix (2009), Wachter (2009), Farhi and Gabaix (2009), Martin (2008), and others. The majority of these studies adopt a representative-agent framework. The few exceptions include Dieckmann and Gallmeyer (2005), Bates (2008), and Dieckmann (2009). The paper closest to ours is Dieckmann (2009), who also studies a model of heterogeneous beliefs about disasters under both complete markets and incomplete markets. He only considers the case of log utility and constant disaster risk, where risk sharing has limited effects on the equity premium.

Our paper builds on the literature of heterogeneous beliefs models. See Basak (2005) for a survey. Recent developments on heterogeneous beliefs and asset pricing include Kogan, Ross, Wang, and Westerfield (2006), Buraschi and Jiltsov (2006), Yan (2008), David (2008), Dumas, Kurshev, and Uppal (2009), Xiong and Yan (2009), among others. Our main finding is related to the results of Kogan, Ross, Wang, and Westerfield (2006), who show that irrational traders can still have large price impact when their wealth becomes negligible. Our affine heterogeneous beliefs model provides a tractable yet flexible framework, through the generalized transform results of Chen and Joslin (2009), to study the implications of general forms of heterogeneity in beliefs about disasters. In the special case with constant disaster probability, we derive closed form solutions for prices, risk premia, and portfolio positions for the cases where relative risk aversion \( \gamma > 1 \). We also provide explicit parameter restrictions for asset prices to be finite.

We also compare our results to models of heterogeneous preferences. Among the works on this topic are Dumas (1989), Wang (1996), Chan and Kogan (2002), and more recently Longstaff and Wang (2008). When agents’ risk aversions are different, we show that the effects on the equity premium are qualitatively similar to the case with heterogeneous beliefs. Moreover, combining lower risk aversion with optimistic beliefs can make the effects of risk sharing on the equity premium particularly strong.

The rest of the paper is organized as follows. Section 2 presents our model of heterogeneous agents and disasters. Section 3 discusses how to bound the beliefs about disasters. Section 4 analyzes the effect of heterogeneous beliefs and risk sharing in a setting with constant disaster risk. The results are then extended to the setting with time-varying disaster risk in Section 5. Section 6 compares the results with the model of heterogeneous risk aversion. Section 7 concludes.
2 Model Setup

We first present the results of the general model where agents have both heterogeneous beliefs and preferences, and the disaster risk is time-varying. Then we review the results for a special case with homogeneous agents and constant disaster risk.

2.1 Disasters and Heterogeneous Agents

We consider a continuous-time, pure exchange economy. There are two agents (A, B), each being the representative of her own class. Agent A believes that the aggregate endowment is \( C_t = e^{c^c_t + c^d_t} \), where \( c^c_t \) is the diffusion component of log aggregate endowment, which follows

\[
dc^c_t = \bar{g} dt + \sigma c dW^c_t,
\]

where \( \bar{g} \) and \( \sigma c \) are the expected growth rate and volatility of consumption without jumps, and \( W^c_t \) is a standard Brownian motion under agent A’s beliefs. The term \( c^d_t \) is a pure jump process whose jumps arrive with stochastic intensity

\[
d\lambda_t = \kappa \left( \bar{\lambda}^A - \lambda_t \right) dt + \sigma \lambda_t dW^\lambda_t,
\]

where \( \bar{\lambda}^A \) is the long-run average jump intensity under A’s beliefs, and \( W^\lambda_t \) is a standard Brownian motion independent of \( W^c_t \). The jumps \( \Delta c^d_t \) have time-invariant distribution \( \nu^A \). We summarize agent A’s beliefs with the probability measure \( \mathbb{P}_A \).

Agent B believes that the probability measure is \( \mathbb{P}_B \), which we shall suppose is equivalent to \( \mathbb{P}_A \). She may disagree about the growth rate of consumption without jumps, the likelihood of disasters or the distribution of the severity of disasters when they occur. We assume that the two agents are aware of each others’ beliefs, but nonetheless “agree to disagree”.

Specifically, agent B’s beliefs are characterized by the Radon-Nikodym derivative \( \eta_t \equiv (d\mathbb{P}_B / d\mathbb{P}_A)_t \).

\[\text{Essentially, two probability measures are equivalent if they agree on the set of impossible events.}\]

\[\text{We do not explicitly model learning about disasters. Given the nature of disasters, such learning will likely be quite slow, and the main source of disagreements will be the priors.}\]
where

\[ \eta_t = e^{a_t + bc^c_t - I_t}, \quad (3) \]

\[ I_t = \int_0^t \left( bg + \frac{1}{2} b^2 \sigma^2_c + \lambda_s \left( \frac{\bar{\lambda}^B}{\lambda^A} - 1 \right) \right) ds, \quad (4) \]

for some constants \( b \) and \( \bar{\lambda}^B > 0 \), and \( a_t \) is a pure jump process whose jumps are coincident with the jumps in \( c^d_t \) and have size

\[ \Delta a_t = \log \left( \frac{\bar{\lambda}^B}{\bar{\lambda}^A} \frac{d\nu^B}{d\nu^A} \right). \quad (5) \]

Here, \( \frac{d\nu^B}{d\nu^A} \) is a function of the disaster size, and reflects the disagreement about the distribution of disaster; \( \frac{d\nu^B}{d\nu^A} \) will be large (small) for the type of disasters that agent B thinks are relatively more (less) likely than agent A.

Intuitively, the Radon-Nikodym derivative expresses the differences in beliefs between the agents by letting agent B assign a higher probability to those states where \( \eta_t \) is high. The terms \( a_t \) and \( bc^c_t \) reflect B’s potential disagreements regarding the likelihood of disasters and the growth rate of consumption, respectively. For example, if \( b > 0 \), then \( \eta_t \) is large in those states where \( c^c_t \) is high, which is equivalent to agent B believing in a higher expected growth rate of consumption without jumps. Similarly, if B believes a disaster of a certain size \( d \) is more likely than A does, either due to a higher intensity in general or a higher probability for disasters of size \( d \) conditional on a disaster occurring, then \( \eta_t \) jumps up when such a disaster occurs. Finally, the integral term \( I_t \) ensures that \( \eta_t \) is a martingale under measure \( \mathbb{P}_A \).

It follows from the specification of \( \eta_t \) in (3-5) that, under agent B’s beliefs, the expected growth rate of consumption without jumps is \( \bar{g} + b \sigma^2_c \), a disaster occurs with intensity \( \lambda_t \times \frac{\bar{\lambda}^B}{\lambda^A} \) (the long run average intensity is \( \bar{\lambda}^B \)), and the disaster size distribution is \( \nu^B \) (which is equivalent to \( \nu^A \)). Now we see that the jumps in \( \eta_t \) specified in (5) are determined by the log likelihood ratio for disasters of different sizes under the two agents’ beliefs. Within this setup, agent B not only can disagree with A on the average frequency of disasters, but also the likelihoods for disasters of different magnitude. Moreover, this setup also has the advantage of remaining within the affine family as \( X_t = (c^c_t, c^d_t, \log \eta_t, \lambda_t) \) follow a jointly affine process, so that the equilibrium can be computed using the generalized transform method in Chen and Joslin (2009).
We assume that the agents are infinitely lived and have constant relative-risk aversion (CRRA) utility over lifetime consumption:

\[ U^i(C^i) = E^i_0 \left[ \int_0^\infty e^{-\rho^i t} \left( \frac{C^i_t}{1-\gamma^i} \right)^{1-\gamma^i} dt \right], \tag{6} \]

for \( i = A, B \). We also assume that markets are complete and agents are endowed with some fixed share of aggregate consumption \((\theta_A, \theta_B = 1 - \theta_A)\).

The equilibrium allocations can be characterized as the solution of the following planner’s problem, specified under the probability measure \( \mathbb{P}_A \),

\[
\max_{C^A_t, C^B_t} E^A_0 \left[ \int_0^\infty e^{-\rho^A t} \left( \frac{C^A_t}{1-\gamma^A} \right)^{1-\gamma^A} + \tilde{\zeta} e^{-\rho^B t} \left( \frac{C^B_t}{1-\gamma^B} \right)^{1-\gamma^B} dt \right],
\tag{7}
\]

subject to

\[ C^A_t + C^B_t = C_t, \tag{8} \]

where \( \tilde{\zeta} \equiv \zeta \eta_t \) is the stochastic Pareto weight for agent B. The first order conditions imply

\[ e^{-\rho^A t} (C^A_t)^{-\gamma^A} = \tilde{\zeta} e^{-\rho^B t} (C^B_t)^{-\gamma^B}, \tag{9} \]

which together with the market clearing condition \( (3) \) gives the equilibrium consumption allocations:

\[
C^A_t = f^A(\hat{\zeta}_t) C_t, \tag{10a} \]
\[
C^B_t = (1 - f^A(\hat{\zeta}_t)) C_t. \tag{10b} \]

where \( \hat{\zeta}_t \equiv e^{(\rho^A - \rho^B)t} C_t^{\gamma^A - \gamma^B} \tilde{\zeta}_t \), and \( f^A \) is an implicit function.

The stochastic discount factor under A’s beliefs, \( M_t \), is given by

\[ M_t = e^{-\rho^A t} (C^A_t)^{-\gamma^A} = e^{-\rho^A t} f^A(\hat{\zeta}_t)^{-\gamma^A} C_t^{-\gamma^A}. \tag{11} \]

Then, we can solve for \( \zeta \) through the lifetime budget constraint for one of the agents (see Cox and Huang (1989)), which is linked to the initial allocation of endowment.

Since our emphasis is on heterogeneous beliefs about disasters, for the remainder of this section we focus on the case where there is no disagreement about the distribution of Brownian shocks,
and the two agents have the same preferences. In this case, $b = 0$, $\gamma_A = \gamma_B = \gamma$, $\rho_A = \rho_B = \rho$. The equilibrium consumption share then simplifies to

$$f^A(\tilde{\zeta}_t) = \frac{1}{1 + \tilde{\zeta}_t^\frac{1}{\gamma}}.$$  \hfill (12)

From the definition of $\Delta a_t$, we see that as a disaster of size $d$ occurs, $\tilde{\zeta}_t$ is multiplied by the likelihood ratio $\lambda^A \frac{d\nu^B}{d\nu^A}(d)$. Thus, if agent B is more pessimistic about a particular type of disaster (because $\lambda^B > \lambda^A$ and/or $\frac{d\nu^B}{d\nu^A}(d) > 1$), she will have a higher weight in the planner’s problem when such a disaster occurs, so that her (relative) consumption increases.

The equilibrium allocations can be implemented through competitive trading in a sequential-trade economy. We consider three types of traded securities: (i) a risk-free money market account, (ii) a claim to aggregate consumption, and (iii) a series (or continuum) of disaster insurance contracts with 1 year maturity, which pay $1 on the maturity date if a disaster of size $d$ occurs within the year.

We can compute the instantaneous riskfree rate from the stochastic discount factor $M_t$,

$$r_t = \rho + \gamma \tilde{g} - \frac{1}{2} \gamma^2 \sigma^2 c - \lambda_t \left( E_t \left[ e^{-\gamma \Delta c^A_t} \frac{f^A(\tilde{\zeta}_t \Delta a_t)}{f^A(\tilde{\zeta}_t)} \right] - 1 \right).$$ \hfill (13)

The price of the aggregate endowment claim is

$$P_t = \int_0^\infty E_t \left[ e^{-\rho \tau} \frac{M_{t+\tau}}{M_t} C_{t+\tau} \right] d\tau,$$ \hfill (14)

which can be viewed as a portfolio of zero coupon consumption claims. It can be shown that the price/consumption ratio only depends on the stochastic weight and the disaster intensity:

$$P_t = C_t h(\lambda_t, \tilde{\zeta}_t).$$ \hfill (15)

In the case where $\lambda_t$ is constant, the price of the consumption claim further reduces to closed form solutions. Similarly, we can also compute the individual agents’ wealth as the prices of their equilibrium consumption streams. See Appendix A for details.

---

*In Section 6 we investigate the case with heterogeneous preferences.*
In order for prices of the aggregate endowment claim to be finite in the heterogeneous-agent economy, it is necessary and sufficient that prices are finite under each agent’s beliefs in a single-agent economy (see Appendix B for a proof). As we show in the appendix, finite prices require that the following two inequalities hold:

\begin{align}
0 &< \kappa^2 - 2\sigma^2_\lambda (\phi^{P_i}(1 - \gamma) - 1), \\
0 &> \kappa \lambda_i \sqrt{\kappa^2 + 2\sigma^2_\lambda (1 - \phi^{P_i}(1 - \gamma))} - \rho + (1 - \gamma)g + \frac{1}{2} (1 - \gamma) \sigma^2_c,
\end{align}

where $\phi^{P_i}$ is the moment generating function for the distribution of jumps in endowment $\nu^i$ under measure $P_i$. The first inequality reflects the fact that the volatility of the disaster intensity cannot be too large relative to the rate of mean reversion. It prevents the convexity effect induced by the potentially large intensity from dominating the discounting. The second inequality reflects the need for enough discounting to counteract the growth.

The disaster insurances are priced similarly through the stochastic discount factor. For the simple case of a single type of disaster, we can compute the price of disaster insurance by considering the counting processes, $N_t$, which counts the number of disasters that have occurred:

\[ M_t P^DI_t = E_t [M_{t+1} 1_{\{N_{t+1} > N_t\}}]. \]

(17)

In the case where $\lambda_t$ is constant, this reduces to a simple expression. For the general case, we use the transform analysis of Duffie, Pan, and Singleton (2000). See Appendix A for details.

Finally, the risk premium for any security under agent $i$’s beliefs ($i = A, B$) is the difference between the expected return under $P_i$ and under the risk-neutral measure $Q_i$. In the case of the aggregate endowment claim, the conditional equity premium under agent $i$’s beliefs is

\[ E_t^{P_i} [R^c] = \gamma \sigma^2_c + \lambda_i^t E_t^{P_i} [\Delta R] - \lambda_i^Q E_t^{Q} [\Delta R], \]

(18)

where $E_t^m [\Delta R]$ is the expected return in a disaster under the measure $m$, $\lambda^A_t = \lambda_t$, and $\lambda^B_t = \lambda_t \times \frac{\lambda_B}{\lambda_A}$. The risk neutral intensity, $\lambda_i^Q \equiv E_t^Q [M_t/M_{t-}] \lambda^i_t$, is determined by the expected jump size of the stochastic discount factor at the time of a disaster, and is the same for both agents under complete markets. The difference between the last two terms is the premium for bearing disaster risk. This
premium is large if the jump-risk premium, \( \frac{\lambda^Q_t}{\lambda^i_t} \), is large, and/or the expected loss in return in a disaster is large, especially under the risk-neutral measure.

It immediately follows that the difference in equity premium under the two agents’ beliefs is

\[
E_t^{P_A}[R^e] - E_t^{P_B}[R^e] = \lambda^A_t E_t^{P_A}[\Delta R] - \lambda^B_t E_t^{P_B}[\Delta R],
\]

which depends on the differences in beliefs about the disaster intensity and the expected return in a disaster. This difference will be small compared to the size of the equity premium when the risk-neutral intensity \( \lambda^Q_t \) is large relative to the actual intensity \( \lambda^i_t \).

In the remainder of the paper, we report the equity premium relative to the probability measure of agent A, \( P_A \). One interpretation for picking \( P_A \) as the reference measure is that A has the correct beliefs, and we are studying the impact of the incorrect beliefs of an optimist on asset prices.

### 2.2 Homogeneous agents and constant disaster risk

When agents have the same preferences and beliefs about disasters, and that the disaster intensity \( \lambda_t \) is constant, we recover the basic version of the representative agent disaster risk model. We now review this case before presenting the results of the heterogeneous-agent model.

The aggregate endowment process is a special case of the process in Section 2 where \( c_t \) is now a pure jump process with constant intensity \( \lambda \) and moment generating function (MGF) \( \phi \) for the jump size distribution. The stochastic discount factor, \( M_t \), is given by \( M_t = e^{-\rho t} C_t^{-\gamma} \). From the stochastic discount factor we can compute the constant risk-free rate

\[
r_t = -\frac{\mathcal{D} M}{M} = \rho + \gamma \bar{g} - \frac{1}{2} \gamma^2 \sigma_c^2 + \lambda (\phi(-\gamma) - 1).
\]

Additionally, the stochastic discount factor allows us to easily compute the risk neutral dynamics, which facilitates the computation and interpretation of excess returns. Under the risk-neutral measure,

\[
dc_t = (\bar{g} - \sigma_c^2 \gamma) dt + \sigma_c dW^Q_t + dJ^Q_t,
\]

where disasters arrive with intensity \( \lambda^Q = \phi(-\gamma) \lambda \) and have distribution with moment generating function \( \phi^Q(s) = \phi(s-\gamma)/\phi(-\gamma) \). When the riskfree rate and disaster intensity are close to zero, the
risk-neutral disaster intensity $\lambda^Q$ can be approximately viewed as the value of a one-year disaster insurance contract that pays $1$ at $t+1$ when a disaster occurs between $t$ and $t+1$.

The risk adjustments for the jumps are quite intuitive. If aggregate consumption drops during a disaster, then $\phi(-\gamma) > 1$ for $\gamma > 0$, so that $\lambda^Q > \lambda$, i.e. disasters occur more frequently under the risk-neutral measure. Moreover, the risk-adjusted distribution of jump size conditional on a disaster satisfies $d\nu^Q/d\nu = e^{-\gamma \Delta c}/\phi(-\gamma)$, which slants the probabilities towards large negative jumps, making severe disasters more likely.

The price of the claim to aggregate dividends is 

$$P_t = E_t \left[ \int_0^\infty e^{-\rho \tau} \frac{M_{t+\tau}}{M_t} C_{t+\tau} d\tau \right] = \frac{C_t}{\theta},$$

where 

$$\theta = \rho - (1 - \gamma)\bar{g} - \frac{1}{2}(1 - \gamma)^2 \sigma_c^2 - \lambda(\phi(1 - \gamma) - 1). \tag{21}$$

Finally, the risk premium on the aggregate consumption claim is 

$$E_t[R^c] = \gamma \sigma_c^2 + \left[ \lambda(\phi(1) - 1) - \lambda^Q(\phi^Q(1) - 1) \right]. \tag{22}$$

The premium for disaster risk reflects both the increased likelihood of disasters under $Q$, $\lambda^Q$ (relative to $\lambda$), and the increased severity of losses for a given disaster under $Q$, $\phi^Q(1) - 1$ (relative to $\phi(1) - 1$). Importantly, the premium rises exponentially with the size of the consumption drops. Thus, a small reduction in the consumption exposure to disasters (especially the most severe ones) can substantially lower the equity premium. This mechanism is key to the results of the heterogeneous agents model.

3 Bounds for Beliefs about Disasters

While the beliefs of individual agents about consumption growth and disasters are not directly observable, historical consumption data together with simple economic restrictions can provide guidance on how extreme these beliefs could be. We define an admissible belief as one that satisfies

\[ \text{The value of the disaster insurance is } D^1_t = e^{-r} \left[ \int_t^{t+1} \lambda^0 e^{-\lambda^0(s-t)} ds \right]. \] 

When $r$ and $\lambda^0$ are close to $0$, $D^1_t \approx \lambda^0$. 

11
Figure 1: **Bounds for extreme beliefs.** The graph plots the p-value for various disaster intensities (bottom axis) and mean growth rates of consumption (top axis) based on 100 years of data.

the following conditions: (i) the belief cannot be rejected by the data at a given significance level $\alpha$ (we choose $\alpha = 5\%$), and (ii) the price of consumption claim under the belief is finite. In the quantitative analysis that follows, we will only consider beliefs that are admissible.

We first use sampling error as a way to judge what types of beliefs are plausible. Specifically, we consider whether an agent with a given null hypothesis about either the growth rate of consumption or the likelihood of disasters would be able to reject the null using 100 years of historical data. Figure 1 plots the p-value associated with different beliefs about the expected growth rate $\bar{g}$ in a Gaussian model (no disasters) and beliefs about $\lambda$ in a constant disaster risk model. The p-value in the Gaussian case is the probability of observing the sample mean growth rate when the true growth rate is $x\%$ lower, an amount specified in the top axis. This p-value is computed based on the assumption that the volatility of consumption growth is $\sigma_c = 2\%$. It falls rapidly, reaching 1% when the expected growth rate is just 0.5% below the sample mean. Such a tiny difference in beliefs about the growth rate has essentially no impact on asset prices in standard settings.\(^6\)

In contrast, since the sampling error for disaster intensity is significantly larger, there is more

---

\(^6\)Cecchetti, Lam, and Mark (2000) and Abel (2002) discuss other sources of disagreement beyond sampling error, which could allow for more disagreements and larger impact on asset pricing. Malmendier and Nagel (2009) argue that individual experiences of macro-economic outcomes can have long-term effects on their preferences and beliefs. 

12
room for heterogeneous beliefs about disasters. We compute the p-value in this case assuming that no disasters have occurred over the last 100 years (the disasters we consider later in the paper are significantly more severe than those observed in the US history). Then the p-value is the probability of observing no disasters assuming the true intensity is consistent with the agent’s beliefs (bottom axis). Figure 1 shows that $\lambda = 3\%$ corresponds to a p-value of 5%. In the homogeneous-agent model, with a relative risk aversion $\gamma = 4$ and assuming a 40% drop of consumption in a disaster, the equity premium will rise from essentially 0 to 8% when the disaster intensity rises from 0 to 3%, which demonstrates how powerful the different beliefs about $\lambda$ can be for asset pricing. If we were to assume there was one disaster in the last 100 years (the Great Depression), then even higher values of $\lambda$ will become admissible.

For disasters that rarely happen, consumption data provide little information about the size of their potential impact. However, we can still obtain restrictions on the beliefs about the jump size distribution (and disaster intensity) via the requirement that prices of the aggregate consumption claim are finite. These conditions are given by (16a–16b) for the general case. If $\lambda_t$ is constant, the conditions simplify to

$$\rho - (1 - \gamma)\bar{g} - \frac{1}{2}(1 - \gamma)^2\sigma_c^2 - \lambda(\phi(1 - \gamma) - 1) > 0,$$

which provides a bound on the moment generating function of the disaster size distribution for given preference parameters and disaster intensity.

The rather loose bounds on the likelihood of disasters and the distribution of disaster size derived from sampling error and economic restrictions highlight the relevance of heterogeneous beliefs about disasters. Next, we investigate how such heterogeneous beliefs affect asset pricing.

4 Heterogeneous Beliefs: Constant Disaster Risk

To cleanly demonstrate the effects of heterogeneous beliefs and the risk-sharing mechanism, we first keep the risk of rare disasters constant, i.e., $\lambda_t = \bar{\lambda}$. We start with two special examples of disagreements about rare disasters, one where agents disagree about the frequency of disasters, the other where they disagree about the size of disasters. We then examine what happens to asset prices when two agents, both believers of disaster risk, coexist in an economy. Finally, we calibrate our
Figure 2: Disagreement about the frequency of disasters. Panel A plots the equity premium under the pessimist’s beliefs as a function of the wealth share of the optimist. Panel B plots the jump-risk premium for the pessimist. We consider two sets of beliefs for the pessimist: \( \lambda^A = 1.7\% \) and \( \lambda^A = 2.5\% \).

model by extracting two sets of beliefs about disaster risk from the US and international experiences of economic disasters.

4.1 Disagreement about the Frequency of Disasters

In the first example, we assume that the disaster size is deterministic, \( \Delta c^{d}_t = \bar{d} \), and the two agents only disagree about the frequency of disasters (\( \lambda \)). We set \( \bar{d} = -0.51 \) so that the MGF \( \phi(-\gamma) \) in this model matches the calibration of Barro (2006) for \( \gamma = 4 \). It implies that aggregate consumption falls by 40% when a disaster occurs.\( ^7 \) Agent A (pessimist) believes that disasters occur with intensity \( \lambda^A = 1.7\% \) (once every 60 years), which is also taken from Barro (2006). The remaining parameters are \( \bar{g} = 2.5\% \), \( \sigma_c = 2\% \), and \( \rho = 3\% \). Agent B (optimist) believes that disasters are much less likely, \( \lambda^B = 0.1\% \) (once every 1000 years), but she agrees with A on the size of disasters as well as the Brownian risk in consumption. She also has the same preferences as agent A.

Figure 2 shows the conditional equity premium and the jump-risk premium under the pessimist’s beliefs. If all the wealth is owned by the pessimist, the equity premium is 4.7\%, and the riskfree

\( ^7 \)This value is higher than the average disaster size in Barro (2006) due to the fact that larger but more rare jumps can have big impact on the MGF, especially when \( \gamma \) is large.
rate is 1.3%. Since the optimist assigns very low probabilities to disasters, if she has all the wealth, the equity premium is only 0.43% under her own beliefs, or −0.21% under the pessimist’s beliefs. Thus, it is not surprising to see the premium fall when the optimist owns more wealth. However, the speed at which the premium declines in Panel A is impressive. When the optimistic agent owns 10% of the total wealth, the equity premium has fallen from 4.7% to 2.7%. When the wealth of the optimist reaches 20%, the equity premium falls to just 1.7%.

We can derive the conditional equity premium as a special case of (18), where the assumption of constant disaster size helps simplify the expression:

\[
E^{F,A}_t[R^c] = \gamma \sigma^2 + \lambda^A \left( \frac{\lambda^Q_t}{\lambda^A} - 1 \right) \left( \frac{h(\tilde{\zeta}_t e^{\theta t} d e^{\theta t})}{h(\tilde{\zeta}_t)} - 1 \right).
\]  

(23)

The first term \( \gamma \sigma^2 \) is the standard compensation for bearing Brownian risk. Heterogeneity has no effect on this term since the agents agree about the brownian risk. Given the value of risk aversion and consumption volatility, this term has negligible effect on the premium. The second term reflects the compensation for disaster risk. It can be further decomposed into three factors: (i) the constant disaster intensity \( \lambda^A \), (ii) the jump-risk premium \( \lambda^Q_t / \lambda^A \), and (iii) the return of the consumption claim in a disaster.

How does the wealth distribution affect the jump-risk premium? From the definition of the stochastic discount factor \( M_t \) and the risk-neutral intensity \( \lambda^Q_t \), it is easy to show

\[
\frac{\lambda^Q_t}{\lambda^A} = e^{-\gamma \Delta c^A_t},
\]

where \( \Delta c^A_t \) is the jump size of the equilibrium log consumption for agent A in a disaster, which could be very different from the jump size in aggregate endowment due to trading. Without trading, as is the case when agent A has all the wealth, \( \Delta c^A_t = \tilde{d} \), which generates a jump-risk premium of 7.7. We have shown earlier that \( \lambda^Q_t \) is approximately the premium of a one-year disaster insurance. Thus, without any risk sharing, the pessimist will be willing to pay an annual premium of 13 cents for $1 of protection against a disaster event that occurs with probability 1.7%.

Since the optimist views disasters as very unlikely events, she is willing to trade away their claims in the future disaster states in exchange for higher consumption in normal times. For example, she will find selling an $1 disaster insurance and collecting a 13 cents premium a lucrative
trade. Such a trade helps reduce the pessimist’s consumption loss in a disaster $\Delta c^A_t$, which in turn lowers the jump-risk premium. However, the optimist’s capacity for underwriting such insurance is limited by her wealth, as she needs to ensure that her consumption/wealth is positive in all future states, including when a disaster occurs (no matter how unlikely such an event is). In fact, she stays away from this limit imposed by the wealth constraint because the more disaster insurance she sells, the more her consumption falls in the disaster states, which makes her less willing to take on additional disaster risk. The more wealth the optimist has, the more disaster insurance she is able to sell without making her consumption too risky when a disaster strikes.

The above mechanism can substantially reduce the disaster risk exposure of the pessimist in equilibrium. Panel B of Figure 2 shows that the jump-risk premium falls rapidly. When the optimist owns 20% of total wealth, the jump-risk premium drops to 4.2. According to equation (23), such a drop in the jump-risk premium alone will cause the equity premium to fall by more than half to 2.2%, which accounts for the majority of the change in the premium (from 4.7% to 1.7%).

Besides the jump-risk premium, the equity premium also depends on the return of the consumption claim in a disaster, which in turn is determined by the consumption loss and changes in the price-consumption ratio. Following a disaster, the risk-free rate drops as the wealth share of the pessimist rises. With CRRA utility, the lower interest rate effect can dominate that of the rise in the risk premium, leading to a higher price-consumption ratio. Since a higher price-consumption ratio partially offsets the drop in aggregate consumption, it makes the return less sensitive to disasters, which will contribute to the drop in equity premium. However, our decomposition above shows that the reduction of the jump-risk premium (due to reduced disaster risk exposure) is the main reason behind the fall in premium.

Can we “counteract” the effect of the optimistic agent and restore the high equity premium by making the pessimist even more pessimistic about disasters? The dash-lines in Figure 2 plot the results when agent $A$ believes that $\lambda = 2.5\%$ (everything else equal), which according to Figure 1 is still admissible (with p-value of 8%). The results are striking. While the equity premium becomes significantly higher (6.8%) when the pessimist owns all the wealth in the economy, it falls to 4.1% with just 2% of total wealth allocated to the optimist (already lower than the previous case with $\lambda^A = 1.7\%$), and is below 1% when the wealth of the optimist exceeds 8.5%. As the wealth share

---

*Wachter (2009) also finds a positive relation between the price-consumption ratio and the equity premium in a representative agent rare disaster model with time-varying disaster probabilities and CRRA utility.*
of the optimist grows higher, the premium can even become negative. The decline in the jump-risk premium is still the main reason behind the lower equity premium. For example, when the optimist has 10% of total wealth, the jump-risk premium falls to 4.0, which will drive the premium down to 3.1% (60% of the total fall).

The reason that the equity premium and the jump-risk premium decline faster is that the amount of risk sharing becomes larger as the beliefs of the two agents become more different, which can quickly dominate the heightened fear of the pessimist. This comparative static exercise has an important implication. When holding the average belief constant (weighted by wealth share), larger disagreement between the two agents can drive the equity premium lower. Thus, the equity premium may not be increasing in the average belief of disaster risk in the market.

To better examine the risk sharing mechanism between agents, we compute their portfolio positions in the aggregate consumption claim, disaster insurance, and the money market account. Calculating these portfolio positions amounts to finding a replicating portfolio that matches the exposure to Brownian shocks and jumps in the individual agents’ wealth processes. Appendix A provides the details. The first thing to notice is that each agent will hold a constant proportion of the consumption claim. Intuitively, this is because they agree on the brownian risk and share it proportionally. Disagreement over disaster risk is resolved through trading in the disaster insurance market, which is financed by the money market account.

We plot the notional value of the disaster insurance sold by the optimist as a fraction of her total wealth in Panel A of Figure 3. The dash-line is the maximum amount of disaster insurance (as a fraction of her wealth) the optimist can sell subject to her budget constraint. When the optimist has very little wealth, the notional value of the disaster insurance she sells is about 35% of her wealth. This value initially rises and then falls as the optimist gains more wealth. The reason is that when the optimist has little wealth, the pessimist has great demand for disaster insurance and is willing to pay a high premium, which induces the optimist to sell more insurance relative to her wealth. As the optimist gets more wealth, risk sharing improves, and the premium on the disaster insurance falls, so that the optimist becomes less aggressive in underwriting the insurance.

By comparing the actual amount of trading to its limit, we can judge whether the risk sharing in equilibrium is too “extreme”. At its peak, the amount of disaster insurance sold by the optimist is about half of the maximum amount that she can underwrite while still keeping her wealth positive.
with probability 1, which might appear reasonable. The caveat is that, in reality, underwriters of disaster insurance will likely be required to collateralize their promises to pay in the disaster states. According to the model, all the wealth is from the claim on future endowment income, which may not be used as collateral (just as labor income cannot be used as collateral). We will revisit the issue of market incompleteness later.

Panel B plots the size of the disaster insurance market (the total notional value normalized by total wealth). Naturally, the size of this market is zero when either agent has all the wealth, and the market is the biggest when wealth is closer to be evenly distributed. At its peak, the notional value of the disaster insurance market is about 16% of the total wealth of the economy. Notice that
the model generates a non-monotonic relation between the size of the disaster insurance market and the equity premium. The premium is high when there is a lot of demand for disaster insurance but little supply, and is low when the opposite is true. In either case, the size of the disaster insurance market will be small.

Panel C plots the equilibrium consumption share of the optimist for different wealth distributions. The 45-degree line corresponds to the case of no trading. The optimist’s consumption share is above the 45-degree line, especially when her wealth is small, suggesting that she is consuming a larger share of total consumption than her endowment in the non-disaster states. However, the price for getting more to consume in normal times is more exposure to the fall in consumption when disaster strikes, which is evident in Panel D. A sign of how aggressive the optimist is in betting against disaster risk is that, when she has little wealth, she will suffer a 70% loss in consumption in the event of a disaster (compared to 40% drop in aggregate consumption). As for the pessimist, the less wealth she possesses, the more disaster insurance she buys relative to her wealth. This will gradually lower her disaster risk exposure, and can eventually turn the disaster insurance into a speculative position — her consumption can jump up as high as 20% in a disaster. This “over-insurance” explains why the equity premium under the pessimist’s beliefs can turn negative when the optimist has most of the wealth.

If we make agent A’s beliefs more pessimistic (e.g. \( \lambda^A = 2.5\% \)), she will pay more for disaster insurance, which presents a better trading opportunity for agent B. Naturally, the amount of disaster insurance sold (both relative to the wealth of the optimistic agent and to total wealth in the economy) becomes higher than the case of milder pessimism, and the equilibrium consumption shares will become more nonlinear. As a result, the pessimist’s consumption loss in a disaster will be reduced at a faster rate (especially near the left boundary), which accelerates the fall in the equity premium.

A final question for this example is whether the effect of risk sharing on the equity premium becomes stronger or weaker as the size of disaster increases. On the one hand, for larger disasters, the equity premium becomes more sensitive to changes in the size of consumption drops, which means the premium will decline more for the same amount of risk sharing between the agents. On the other hand, the optimist will be increasingly reluctant to take on extra losses in the disaster state because her marginal utility rises exponentially in the (log) size of consumption losses. To
study the net effects, we increase the size of disasters, but keep the risk premium for the pessimist in the single-agent and the relative difference in beliefs unchanged (by lowering \( \lambda^A \) and keeping \( \lambda^B / \lambda^A \) fixed). Our results (not reported) show that the second effect dominates. The decline in equity premium becomes closer to linear as \( \bar{d} \) gets larger (in absolute value), and the amount of risk sharing becomes smaller.

4.2 Disagreement about the Size of Disasters

The second example we study is on disagreement about the distribution of disaster size. For simplicity, we assume that the drop in aggregate consumption in a disaster follows a binomial distribution, with the possible drops being 10% and 40%. Both agents agree on the intensity of a disaster (\( \lambda = 1.7\% \)). Agent A (pessimist) assigns a 99% probability to a 40% drop in aggregate consumption, thus having essentially the same beliefs as in the previous example. On the contrary, agent B (optimist) only assigns 1% probability to a 40% drop, but 99% probability to a 10% drop. The rest of the parameter values are the same as in the first example.

Figure 4 (solid lines) plots the conditional equity premium and jump-risk premium under the
pessimist’s beliefs. When the pessimist has all the wealth, the equity premium is 4.6% (almost the same as in the first example). Again, the equity premium falls rapidly as we starts to shift wealth to the optimist. The premium falls by almost half to 2.4% when the optimist owns just 5% of total wealth, and becomes 1.4% when the optimist’s share of total wealth grows to 10%. Similarly, the jump-risk premium falls from 7.6 to 4.5 with the optimist’s wealth share reaching 10%, which by itself will lower the premium to 2.4%.

These results show that, in terms of asset pricing, introducing an agent who disagrees about the severity of disasters is similar to having one who disagrees about the frequency of disasters. Even though the two agents agree on the intensity of disasters in general, they actually strongly disagree about the intensity of disasters of a specific magnitude. For example, under A’s beliefs, the intensity of a big disaster is $1.7\% \times 99\% = 1.68\%$, which is 99 times the intensity of such a disaster under B’s beliefs. The opposite is true for small disasters. Thus, B will aggressively insure A against big disasters, while A insure B against small disasters. For agent A, the effect of the reduction in consumption loss in a big disaster dominates that of the increased loss in a small disaster, which drives down the equity premium exponentially. Such trading can also become speculative when B has most of the wealth: agent A will take on so much loss in a small disaster that the jump-risk premium rises up again.

Naturally, we expect that the agents will be less aggressive in trading disaster insurances when there is less disagreement on the size of disasters, and that the effect of risk sharing on the risk premium will become smaller. The case of “less disagreement” in Figure 4 confirms this intuition. In this case, we assume that the two agents assign 90% probability (as opposed to 99%) to one of the two disaster sizes. While the equity premium still falls rapidly near the left boundary, the pace is slower than in the previous case. Similarly, we see a slower decline in the jump-risk premium.

4.3 When Two Pessimists Meet

The examples we have considered so far have one common feature: the new agent we are bringing into the economy has more optimistic beliefs about disaster risk, in the sense that the distribution of consumption growth under her beliefs first-order stochastically dominates that of the other’s, and that the equity premium is significantly lower when she owns all the wealth. However, the key to generating aggressive risk sharing is not that the new agent demands a lower equity premium,
In order to highlight this insight, let's consider the following example, where both agents believe that disaster risk accounts for the majority of the equity premium. The key difference in their beliefs is that one agent believes that disasters are rare but big, while the other thinks disasters are more frequent but less severe. Specifically, we assume that disasters can cause aggregate consumption drops of a 30% or 40%. Agent A believes that $\lambda_A = 1.7\%$, and assigns 99% probability to the bigger disaster. B believes that $\lambda_B = 4.2\%$, and assigns 99% probability to the smaller disaster.

By themselves, the two agents both demand high equity premium. We have chosen $\lambda^B$ so
that, under the beliefs of agent A, the equity premium is 4.6% whether A or B has all the wealth. However, they have significant disagreement on the exact magnitude of the disaster. For example, agent A believes that the intensity of the big disaster is 1.68%, while B believes that the intensity is only 0.04%. Such disagreement generates a lot of demand for risk sharing. As we see in Panel A of Figure [5], the conditional equity premium falls rapidly as the wealth share of agent B moves away from the two boundaries. In fact, the premium will be below 2% when B owns between 9% and 99% of total wealth. In Panel B, the jump risk premium also falls by half from 7.6 and 10 on the two boundaries when B’s wealth share moves from 0% and 100% to 25% and 91%, respectively.

To get more information on the risk sharing mechanism, in Panel C and D we examine the equilibrium consumption changes for the individual agents during a small or big disaster. Since agent A assigns a low probability to the small disaster, she insures agent B against this type of disasters. As a result, her consumption loss in such a disaster exceeds that of the aggregate endowment (-30%), and it increases with the wealth share of agent B. When B has almost all the wealth in the economy, agent A sells so much small disaster insurance to B that her own consumption can fall by as much as 82% when such a disaster occurs. As a result, agent B is able to reduce her risk exposure to small disasters significantly. In fact, her consumption actually jumps up in a small disaster when she owns less than 75% of total wealth, sometimes by over 100% (when her wealth share is small).

The opposite is true in Panel D. As agent B insures A against big disasters, she experiences bigger consumption losses in such a disaster than the aggregate endowment (-40%). The equilibrium consumption changes of the two agents are less extreme compared to the case of small disasters, which is due to two reasons. First, the relative disagreement on big disasters is smaller than on small disasters. Second, the insurance against larger disasters is more expensive, so that agent A’s ability to purchase disaster insurance is more constrained by her wealth.

We can take the insight from this example one step further. Suppose the new agent added into the economy is even more pessimistic about disaster risk than the majority wealth holder. The new agent assigns higher probabilities to more severe disasters, so that she would demand a higher equity premium on her own. However, the equity premium will still decline rapidly when we allocate a small amount of wealth to the new agent, because despite her pessimism, she will be able to insure the old agent against the smaller disasters.
4.4 Calibrating Disagreement: Is the US Special?

Having considered a series of special examples of heterogeneous beliefs, we now extend the analysis to a more realistic model of beliefs on disasters. The way we calibrate the beliefs of the two types of agents is as follows. Agent A believes that the US is no different from the rest of the world in its disaster risk exposure. Hence her beliefs are calibrated using cross-country consumption data. Agent B, on the other hand, believes that the US is special. She forms her beliefs on disaster risk using only the US consumption data.

An important contribution of Barro (2006) is to provide detailed accounts of the major consumption declines across 35 countries in the twentieth century. Rather than directly using the empirical distribution from Barro (2006), we estimate a truncated Gamma distribution for the log jump size from Barro’s data using maximum likelihood (MLE). Our estimation is based on the assumption that all the disasters in the sample were independent, and that the consumption declines occurred instantly. We also bound the jump size between $-5\%$ and $-75\%$. In comparison, the smallest and largest declines in per capita GDP in Barro’s sample are $15\%$ and $64\%$, respectively. The disaster intensity under A’s beliefs is still $\lambda^A = 1.7\%$. The remaining parameters are: the mean growth rate and volatility of consumption without a disaster, $\bar{g} = 2.5\%$ and $\sigma_c = 2\%$, which are consistent with the US consumption data post WWII.

As for agent B, we assume that she agrees with the values of $\bar{g}$ and $\sigma_c$, but we estimate the truncated Gamma distribution of disaster size using MLE from annual per-capita consumption data in the US 1890-2008. Over the sample of 119 years, there are three years where consumption falls by over $5\%$. Thus, we set $\lambda^B = 3/119 = 2.5\%$. Alternatively, we can also jointly estimate $\lambda^B$ and the jump size distribution.

Panel A of Figure plots the probability density functions of the log jump size distributions for the two agents, which are very different from each other. The solid line is the distribution fitted to the international data on disasters. The average log drop is $0.36$, which is equivalent to $30\%$ drop.

---

9 The truncated Gamma distribution has PDF $f(d; \alpha, \beta | d_{\min}, d_{\max}) = f(d; \alpha, \beta) / (F(d_{\max}; \alpha, \beta) - F(d_{\min}; \alpha, \beta))$, where $f(x; \alpha, \beta)$ and $F(x; \alpha, \beta)$ are the PDF and CDF of the standard Gamma distribution with shape parameter $\alpha$ and scale parameter $\beta$.

10 These assumptions are debatable. For example, many of the major declines cross European countries are in WWI and WWII. Moreover, many of the declines spanned several years. See Donaldson and Mehra (2008) for more discussions on the issue of observation frequency.

Figure 6: Calibrated Disagreements: International vs US Experiences. Panel A plots the truncated Gamma distribution of disaster size for the two agents. Panel B plots the equilibrium consumption drops for the two agents given the size of the disaster. Panel C and D plot the equity premium and jump-risk premium under A’s beliefs.

In the level of consumption. In the US data, the average drop in log consumption is only 0.075, or 7.3% in level. In addition, agent A’s distribution has a much fatter left tail than B. Thus, while A assigns significantly higher probabilities than B to large disasters (where consumption drops by 15% or more), agent B assigns more probabilities to small disasters, especially those ranging from 5 to 12%. In fact, agent B’s beliefs are close to the calibration adopted by Longstaff and Piazzesi (2004), who assume that the jump in aggregate consumption during a disaster is 10%.

The differences in beliefs lead the two agents to insure each other against the types of disasters they fear more about, and the trading can be implemented using a continuum of disaster insurance contracts with coverage specific to the various disaster sizes. Panel B plots drops in the equilibrium
consumption (level) for the two agents when disasters of different sizes occur, assuming that agent B owns 10% of total wealth. The graph shows that through disaster insurances, agent A is able to reduce her consumption loss in large disasters (comparing the solid line to the dotted line). For example, her own consumption will only fall by 24% in a disaster where aggregate consumption falls by 40%, a sizable reduction especially considering the small amount of wealth that agent B has. At the same time, she also provides insurances to B on smaller disasters, which increases her consumption losses when such disasters strike. Agent B’s consumption changes are close to a mirror image of agent A’s. However, the changes are magnified both for large and small disasters due to her small wealth share.

Panel C shows the by-now familiar exponential drop in the equity premium as the wealth share of agent B increases. The equity premium is 4.4% when all the wealth is owned by the agents who form their beliefs about disasters based on international data, but drops to 2.0% when just 10% of total wealth is allocated to the agents who form their beliefs using only the US data. The main reason for the lower equity premium is again due to the decrease of the jump-risk premium (Panel D), which falls from 6.5 to 4.0 when agent B’s wealth share rises to 10%. This effect alone drives the equity premium down to 2.4%. Notice that the jump-risk premium is no longer monotonic in the wealth share of agent B. This is because when agent A has little wealth, she would be betting against small disasters so aggressively that the big losses for her during small disasters can cause the jump-risk premium to rise again.

In summary, this calibrated model of heterogeneous beliefs demonstrates that our main finding that risk sharing quickly reduces the equity premium is robust to general specifications of beliefs and is quantitatively important. Next, we conclude this section by discussing the implications of heterogeneous beliefs for survival.

4.5 Survival

Models with heterogeneous beliefs (or preferences) often have the undesirable property of non-stationarity in the sense that one type of agents will dominate in the long-run (a notable exception is (Chan and Kogan 2002)). Our model also has the property that the agent with correct beliefs
Table 1: Survival of Agents who Disagree about the Frequency of Disasters. This table provides the redistribution of wealth across a 50 year horizon. Future relative wealth is determined only by the initial wealth, the time horizon, and the number of disasters that occur. The model specification is provided in Section 4.1. The top panel provides the possible wealth redistributions throughout time. The bottom panel provides the probability (under each Agent’s beliefs) for different numbers of disasters occurring.

will dominate in the long run.\(^{12}\) We now show that although agents with incorrect beliefs may not have permanent effects on asset prices, their effects may be long-lived in the sense that agents can retain, and even build, wealth over long horizons.

With disaster intensity \( \lambda_t \) being constant, to analyze the wealth distribution over time, we need only consider the distribution of the stochastic Pareto weight, \( \zeta_t \). We consider the first example from Section 4 where disagreement is over the frequency of disasters of fixed size. From (3), we see that \( \zeta_t \) has a stochastic component, whereby the Pareto weight (and thus wealth) of the pessimistic agent will jump up when a disaster occurs. This is because the pessimist receives insurance payments from the optimist in a disaster. However, regardless of the occurrence of disasters, there is also a deterministic component in \( \zeta_t \), whereby the optimist has a deterministic weight increase (and thus her relative wealth increases) which comes from collecting the disaster insurance premium. Thus, even when the pessimist has correct beliefs, her relative wealth will decrease outside of disasters. Since disasters are rare, it will be common to have extended periods without disasters, during which time an optimistic agent will gain relative wealth.

\(^{12}\)This is easy to see, since when \( P^A = P \), the data-generating measure, the stochastic Pareto weight \( \zeta_t \) is a \( P \)-martingale. It then follows that \( \log \zeta_t \) is a \( P \)-supermartingale and that \( \log \zeta_t \to -\infty \) almost surely.
Table 1 presents a summary of the conditional distribution of wealth after 50 years for various initial wealth distributions. We report the results under the assumption that either the pessimist or optimist has correct beliefs. If the number of disasters is either 0 or 1, the wealth of the agents remain relatively close to the original distribution. We see that the optimist is likely to retain wealth for long periods of time and will only be wiped out with the occurrence of several disasters, which is unlikely regardless of whose beliefs are correct.

The survival results presented thus far stand in sharp contrast to survival in models of disagreement over Brownian consumption growth. As discussed in Section 3, it is possible to raise the equity premium under the true measure if there are agents who are pessimistic about the growth rate of consumption. For example, if the volatility of consumption is $\sigma_c = 2.0\%$, two types of agents have $\gamma = 4$ and $\rho = 0.1$, one believing (correctly) consumption growth is 2%, the other believing it is 0% (no disasters), then the equity premium will be roughly 2% when the pessimist controls most of the wealth in the economy. However, even if the pessimist controls 99% of the wealth initially, her wealth share will be reduced to less than 1% after 50 years with a probability of 93.5%. Thus, even a very small amount of agents with correct beliefs will quickly dominate the economy in the Gaussian setting.

While the above example suggests that optimistic agents gain wealth share outside of disasters, this may not be true in general cases. A key factor behind the dynamics of the wealth distribution is the deterministic component of the log Pareto weight, which depends on the difference in the two agents’ beliefs about disaster intensities, but not the distribution of disaster size. In the example of Section 4.4, the “optimistic” agent believes disasters occur more frequently but are less likely to be severe. Thus, outside of disasters, this agent will lose wealth as she spends more on buying insurances against small disasters than she makes from selling insurances against large disasters. She will also lose wealth share in big disasters, but will gain wealth share in small disasters. In such cases, survival at moderately long horizons becomes more sensitive to the exact specification of the disagreement.
5 Heterogeneous Beliefs: Time-varying Disaster Risk

In the previous section we have analyzed in depth the case where disaster intensity $\lambda_t$ is constant. Now we extend the analysis to allow the risk of disasters and the amount of disagreements about disasters to vary over time, which not only makes the model more realistic, but also has important implications for the dynamics of asset prices. The basic intuition that heterogeneous beliefs generate strong risk sharing still holds. Thus, we will focus more on the dynamics of the wealth distribution and equity premium.

Our calibration of the intensity process $\lambda_t$ is as follows. First, the long-run mean intensity of disasters under the two agents’ beliefs are $\bar{\lambda}^A = 1.7\%$ and $\bar{\lambda}^B = 0.1\%$. Next, following Wachter (2009), we set the speed of mean reversion $\kappa = 0.142$ (with a half life of 4.9 years). The volatility parameter is $\sigma_\lambda = 0.05$, so that the Feller condition is satisfied. For simplicity, we assume that the size of disasters is constant, $\bar{d} = -0.51$, the same as in Section 4.1. The remaining preference parameters are also the same as in the constant disaster risk case.

After solving the model, we simulate paths of disaster intensity $\lambda_t$ along with the jump component of aggregate endowment $c_t^d$ under agent A’s beliefs, which together determine the evolution of the stochastic Pareto weight $\tilde{\zeta}_t$. Then, along the simulated paths, we compute the equilibrium wealth fraction of agent A, $w_t^A$, and the conditional equity premium under A’s beliefs, $E_t^A[R^e]$. In each simulation we start with $\lambda_0 = 1.7\%$ and set the initial wealth share of agent A $w_0^A = 90\%$. The results from two of the simulations are reported in Figure 7.

Panel A plots the time series of $\lambda_t$ from the two simulations. Due to the choice of $\kappa$, the disaster intensity is fairly persistent, and shows considerable variation over time. For example, in Simulation I (solid line), $\lambda_t$ ranges from 0.2% to 6.7% over 50 years. What are not shown in this graph are the occurrences of disasters. In Simulation I, disasters occur three times within the first 50 years, around year 13, 18, and 46. In Simulation II, there are no disasters.

The evolution of the wealth distribution largely follows that of the disaster intensity when there are no disasters, but can change dramatically if a disaster occurs. As we see in Panel B, for Simulation I, the wealth share of agent A jumps up each time a disaster strikes. This is because the disaster insurance that A (pessimist) purchases from B (optimist) pays off at such times, causing

\footnote{The Feller condition, $2\kappa\bar{\lambda}^A > \sigma_\lambda^2$, ensures that $\lambda_t$ will remain positive under agent A’s beliefs.}
the wealth of A to increase relative to B. The size of the jump in $w_A^t$ is bigger in the first two disasters, which is due to two reasons. First, during the first two disasters, the wealth distribution is not too concentrated in the hands of agent A, so that agent B can still provide a fair amount of risk sharing. Second, the first disaster occurs at times when $\lambda_t$ is relatively high, i.e., they are less of a “surprise”. Thus, agent A will have bought more insurance against the disaster beforehand, causing her wealth share to rise more after the disaster.

When there are no disasters, holding $\lambda_t$ fixed, agent A is losing wealth share to B as she pays B the premium for disaster insurance. This effect is captured by the negative drift in the Radon-Nikodym derivative $\eta_t$ (see equation (3)), and is stronger when $\lambda_t$ is larger. In addition, as $\lambda_t$ falls
(rises), the value of the disaster insurance that agent A owns falls (rises), causing her wealth to fall (rise) relative to agent B, who is short the disaster insurance.

Panel C plots the conditional equity premium under A’s beliefs. In Simulation II (no disasters), despite the fact that the optimistic agent never owns more than 15% of total wealth and that disaster intensity $\lambda_t$ shows considerable variation over the period, the equity premium is below 2% nearly 90% of the time. This result confirms our findings in the case of constant disaster risk, namely the risk sharing between the agents keeps the premium at low levels during periods without disasters.

When disasters do occur, the picture of the equity premium becomes very different. In Simulation I, the equity premium shows large variation, ranging from 0.5% to 9.2%. There are three disasters within 50 years, which is somewhat “unusual” even under agent A’s beliefs. As a result, agent B loses wealth relatively quickly, reducing her risk sharing capacity and driving up the equity premium. Moreover, the equity premium also becomes more sensitive to the fluctuations in $\lambda_t$ when agent B has little wealth. This effect is evident in the sharp contrast of the volatility of the equity premium prior to the first disaster (when the wealth share of agent B is still relatively high) and afterwards.

A final feature that stands out in the plot of the equity premium from Simulation I is the big spike in the premium following the first disaster around year 13. Since the disaster occurs at a time when $\lambda_t$ is high while the wealth share of agent B is not too small, the disaster causes the wealth distribution to change dramatically, which together with the high $\lambda_t$ makes the jump in the equity premium particularly pronounced.

### 6 Heterogeneous Risk Aversion

Intuitively, besides heterogeneous beliefs, heterogeneity in risk aversion should also be able to induce risk sharing among agents and reduce the equity premium in equilibrium. Recall that the jump-risk premium is $\lambda_t^Q/\lambda_t^i = e^{-\gamma \Delta c_i^t}$, which is not only sensitive to changes in individual consumption loss $\Delta c_i^t$, but also to changes in the relative risk aversion $\gamma$. Thus, we expect that heterogeneous risk aversion can have similar effects on the equity premium as heterogeneous beliefs about disasters.

To check this intuition, we consider the following special case of the model. Agent A is the same as in the example of Section 4.1: $\lambda^A = 1.7\%$, $\gamma_A = 4$. Agent B has identical beliefs about disasters
Figure 8: The effects of heterogeneous risk aversion. This graph plots the equity premium when the two agents have different risk aversion: $\gamma_A = 4, \gamma_B = 2$. Their beliefs about disasters are specified in the legend. Disaster size is constant.

but is less risk averse: $\lambda^B = 1.7\%, \gamma_B < \gamma_A$. Figure 8 plots the equity premium as a function of agent B’s wealth share for $\gamma_B = 2$. The equity premium does decline as agent B’s wealth share rises. However, the decline is slow and closer to being linear. In order for the equity premium to fall below 2%, the wealth share of the less risk-averse agent needs to rise to 60%. The decline in the equity premium becomes faster as we further reduce the risk aversion of agent B (not reported here), but the non-linearity is still less pronounced than in the cases with heterogeneous beliefs.

Combining heterogeneous beliefs about disasters and different risk aversion can amplify risk sharing and accelerate the decline in the equity premium. As shown in the figure, if agent B believes disasters are less likely than does agent A, and she happens to be less risk averse, the equity premium falls faster. Consider the case where agent B believes disasters only occur once every hundred years ($\lambda^B = 1.0\%$). With 20% of total wealth, she drives the equity premium down by almost a half to 2.5%. If $\lambda^B = 0.1\%$, the decline in the equity premium will be even more dramatic.
7 Concluding Remarks

We demonstrate the equilibrium effects of reasonable disagreement about disasters on risk premia and trading activities. When agents disagree about disaster risk, they will insure each other against the types of disasters they fear most. Because of the highly non-linear effect of disaster size on risk premia, the risk sharing provided by a small amount of agents with heterogeneous beliefs can significantly attenuate the effect of disasters on the equity premium. The model also has several important implications for the dynamics of asset prices.

We should emphasize that our results do not necessarily diminish the importance of disaster risk for the equity premium. The effectiveness of risk sharing hinges on complete markets. The amount of disaster insurance being traded in our model, while still within the limit imposed by the budget constraint, can be difficult to implement in practice due to moral hazard. Even exchange trading and daily mark-to-market will not eliminate the counterparty risks associated with these contracts, because disasters will lead to sudden large changes in prices. From this perspective, our results highlight the importance of incorporating market incompleteness in disaster risk models.

It would be very useful to study what happens to asset prices when we limit the risk sharing among investors with heterogeneous beliefs about disasters, perhaps by imposing transaction costs, borrowing constraints, and short-sales constraints\textsuperscript{14} as in Heaton and Lucas (1996).

Another possible way to reduce the effects of heterogeneous beliefs is through ambiguity aversion. As Hansen (2007) and Hansen and Sargent (2009) show, if investors are ambiguity averse, they deal with model/parameter uncertainty by slanting their beliefs pessimistically. In the case with disaster risk, confronting investors with the same model uncertainty facing econometricians could lead them to behave as if they believe the disaster probabilities are high, even though their actual priors might suggest otherwise. This mechanism could reduce the heterogeneity of the distorted beliefs among agents, thus limiting the effects of risk sharing. We leave these implications to future research.

\textsuperscript{14}Since the primary risk in the aggregate endowment claim is disaster risk, shorting the stock might serve as a close substitute to buying disaster insurance.
Appendix

A Securities’ prices and portfolio positions

In this appendix we compute the prices of the claim on aggregate endowment (stock), the claim on individual agents’ consumption streams (agents’ personal wealth), disaster insurance, and the equilibrium portfolio positions. We begin with the general setting of time-varying disaster intensity. To concentrate on the effects of heterogeneous beliefs, we assume that the two agents have the same relative risk aversion \( \gamma \).

A.1 Aggregate and individual consumption claim prices: general setting

The price of the aggregate endowment claim is

\[
P_t = \int_0^\infty E_t \left[ \frac{M_{t+T}}{M_t} C_{t+T} \right] dT,
\]

where \( M_t \) is the stochastic discount factor

\[
M_t = e^{-\rho t} C_t^{-\gamma} \left( 1 + (\zeta_0 e^{\log \eta_t})^{\frac{1}{\gamma}} \right)^\gamma.
\]

This price can be viewed as a portfolio of zero coupon aggregate consumption claims

\[
M_t P_t^{t+T} = E_t[M_{t+T} C_{t+T}] = e^{-\rho(T+t)} e^{T[\bar{g}(1-\gamma)+\frac{1}{2}\sigma_2^2(1-\gamma)^2]e^{(1-\gamma)c_t}} \times E_t \left[ e^{(1-\gamma)c_{t+T}} \left( 1 + (\zeta_0 e^{\log \eta_{t+T}})^{\frac{1}{\gamma}} \right)^\gamma \right].
\]

Under our assumption of integer \( \gamma \), the final term will be a sum of expectations of the form

\[
E_t[e^{(1-\gamma)c_{t+T} + \beta_t \log \eta_{t+T}}] = e^{A_t(T) + (1-\gamma)c_t + \beta_t \log \eta + B_t(T)\lambda_t},
\]
where \((A_i, B_i)\) satisfy a simplified version of the familiar Riccati differential equations

\[
\dot{B}_i = -\frac{\bar{\lambda}}{\lambda} B_i - \kappa B_i + \frac{\sigma_2^2}{2} B_i^2 + (\phi((1 - \gamma, \beta_i)) - 1) , \quad B_0(0) = 0, \tag{A.3a}
\]

\[
\dot{A}_i = \kappa \theta B_i , \quad A_i(0) = 0, \tag{A.3b}
\]

where \(\phi\) is the moment generating function of jumps in \(\langle c^d_t, a_t \rangle\).

It follows that price/consumption ratio of the zero-coupon equity varies only with the stochastic weight \(\tilde{\zeta}_t\) and the disaster intensity:

\[
P^{t+T}_t = C_t h^T(\lambda_t, \tilde{\zeta}_t). \tag{A.4}
\]

Next, agent A’s wealth \(P^A_t = \int_0^\infty E_t \left[ M_t P^A_{t+T} \right] dT \) at time \(t\) is a portfolio of her zero coupon consumption claims

\[
M_t P^{A,t+T}_t = E_t [M_t C^A_{t+T}]
= e^{-\rho(t+T)} e^{T[\phi(1-\gamma) + \frac{1}{2} \sigma_2^2 (1-\gamma)^2]} e^{(1-\gamma) \zeta_0} \times E_t \left[ e^{(1-\gamma) c^d_{t+T}} \left( 1 + (\zeta_0 e^{\log \eta} \gamma)^{1/\gamma} \right)^{\gamma-1} \right].
\]

We can compute agent A’s wealth process by making a similar binomial expansion as in the case of \(P_t\), and then computing the expectation concerning the same affine jump diffusion process. Finally, the wealth process of agent B is simply \(P^B_t = P_t - P^A_t\).

### A.2 Special case: constant disaster risk

Closed form expressions can now be obtained in the special case of constant disaster intensity and constant disaster size. Let’s denote \(\tilde{\zeta}_t \equiv \zeta_0 e^{\log \eta}\). Again by expanding the binomial for the cases with integer \(\gamma\),

\[
E_t [M_{t+T} C_{t+T}] = e^{-\rho(t+T)} E_t \left[ \left( 1 + (\tilde{\zeta}_{t+T})^{1/\gamma} \right)^\gamma C_{t+T}^{1-\gamma} \right]
= e^{-\rho(t+T)} C_t^{1-\gamma} \sum_{k=0}^{\gamma} \binom{\gamma}{k} E_t \left[ (\tilde{\zeta}_{t+T})^{k/\gamma} C_{t+T}^{1-\gamma} \right].
\]

35
Plugging in the explicit expressions for aggregate consumption $C_t$, the stochastic discount factor $M_t$, and performing the simple affine jump diffusion expectation we obtain

$$P_{t}^{t+T} = C_t \sum_{k=0}^{\gamma} \alpha_{k,t} e^{-\beta_{k} T},$$  \hspace{1cm} (A.5)

with

$$\alpha_{k,t} \equiv \left( \begin{array}{c} \gamma \\ k \end{array} \right) \frac{\left(\tilde{\zeta}_{t}\right)^{k/\gamma}}{(1 + \left(\tilde{\zeta}_{t}\right)^{1/\gamma})^\gamma},$$  \hspace{1cm} (A.6a)

$$\beta_{k} \equiv \rho + (\gamma - 1)\bar{g} - \frac{1}{2} \sigma^{2}(\gamma - 1)^2 - \lambda (e^{(\gamma - 1)\Delta a} - 1) + \frac{\bar{\lambda} k}{\gamma} (e^{\Delta a} - 1),$$  \hspace{1cm} (A.6b)

where $\Delta a$ is given in (5).

Finally, integrating over time $T$ yields the explicit price of aggregate endowment claim

$$P_{t} = \int_{0}^{\infty} P_{t}^{t+T} dT = C_t \sum_{k=0}^{\gamma} \frac{\alpha_{k,t}}{\beta_{k}}.$$  \hspace{1cm} (A.7)

The restriction $\beta_{k}^{A} > 0$ is needed to ensure finite value for $P_{t}$. We will come back to this type of restriction below.

By identical approach, we obtain the price of agent A’s consumption claim (i.e. her wealth process)

$$P_{t}^{A} = \int_{0}^{\infty} P_{t}^{A,t+T} dT = C_t \sum_{k=0}^{\gamma - 1} \frac{\alpha_{k,t}^{A}}{\beta_{k}},$$  \hspace{1cm} (A.8)

where $\beta_{k}$ remains the same as above and

$$\alpha_{k,t}^{A} \equiv \left( \begin{array}{c} \gamma - 1 \\ k \end{array} \right) \frac{\left(\tilde{\zeta}_{t}\right)^{k/\gamma}}{(1 + \left(\tilde{\zeta}_{t}\right)^{1/\gamma})^\gamma}.$$  \hspace{1cm} (A.9)

**Price of disaster insurance**

Let $P_{t,t+T}^{DI}$ denotes the price of disaster insurance which pays $1 at maturity time $t + T$ if there was at least one disaster taking place in the time interval $(t, t + T)$. In the main text we consider
disaster insurance $P_t^{DI}$ of maturity $T = 1$ in particular.

$$P_{t,t+T}^{DI} = E_t \left[ \frac{M_{t+T} - M_t}{M_t} \mathbf{1}_{\{N_{t+T} > N_t\}} \right]$$

$$= \frac{e^{-\rho T}}{(C_t^A)^{-\gamma}} E_t \left[ (C_t^{A})^{-\gamma} \mathbf{1}_{\{N_{t+T} > N_t\}} \right]$$

$$= e^{(-\rho - \gamma \bar{g} + \frac{1}{2} \gamma^2 \sigma_c^2) T} \left( 1 + (\tilde{\zeta}_t^{T})^{1/\gamma} \right) E_t \left[ e^{\gamma d N_t} (1 + (\tilde{\zeta}_t^{T})^{1/\gamma}) e^{(\Delta a \Delta N_T - \bar{\lambda} T (e^{\Delta a} - 1)) / \gamma} \mathbf{1}_{\{\Delta N_T > 0\}} \right]$$

$$= \frac{e^{(-\rho - \gamma \bar{g} + \frac{1}{2} \gamma^2 \sigma_c^2) T}}{(1 + (\tilde{\zeta}_t^{T})^{1/\gamma})} \left\{ E_t \left[ e^{\gamma d N_T} (1 + (\tilde{\zeta}_t^{T})^{1/\gamma}) e^{(\Delta a \Delta N_T - \bar{\lambda} T (e^{\Delta a} - 1)) / \gamma} \right] - (1 + (\tilde{\zeta}_t^{T})^{1/\gamma} e^{-\bar{\lambda} T (e^{\Delta a} - 1) / \gamma} \text{Prob}(\Delta N_T = 0) \right\}, \quad \text{(A.10)}$$

where $\Delta N_T \equiv N_{t+T} - N_t$ is number of disasters taking place in $[t, t + T]$, and $\text{Prob}(\Delta N_T = 0) = e^{-\bar{\lambda} T}$ is the probability that no such disaster did happen. Again by expanding the binomial $(1 + (\tilde{\zeta}_t^{T})^{1/\gamma} e^{(\Delta a \Delta N_T - \bar{\lambda} T (e^{\Delta a} - 1)) / \gamma})$, and then computing the expectation of each resulting term, we obtain

$$P_{t,t+T}^{DI} = \frac{a_T}{(1 + (\tilde{\zeta}_t^{T})^{1/\gamma})} \left\{ \sum_{k=0}^{\gamma} b_{k,T} (\tilde{\zeta}_t^{T})^{k/\gamma} - e^{-\bar{\lambda} T (1 + (\tilde{\zeta}_t^{T})^{1/\gamma} e^{-\bar{\lambda} T (e^{\Delta a} - 1) / \gamma})} \right\}, \quad \text{(A.10)}$$

where

$$a_T = e^{(-\rho - \gamma \bar{g} + \frac{1}{2} \gamma^2 \sigma_c^2) T}, \quad \text{(A.11a)}$$

$$b_{k,T} = \left( \begin{array}{c} \gamma \\ k \end{array} \right) e^{-\bar{\lambda} k T (e^{\Delta a} - 1) / \gamma} e^{\bar{\lambda} T e^{\gamma d (\Delta a)/\gamma} (e^{\Delta a} - 1)}. \quad \text{(A.11b)}$$

**Equilibrium portfolio positions**

In the current case of constant jump size with two dimensions of uncertainties (Brownian motion and disaster jump), the market is complete when agents are allowed to trade contingent claims on aggregate consumption (stock) $P_t$, money market account $RF_B_t$ and disaster insurance $P_t^{DI}$. We can use generalized Ito lemma on jump-diffusion price processes $P_t^A, P_t, P_t^{DI}$ to write generically
(where indexes \(b\) and \(j\) respectively correspond to Brownian and jump shocks)

\[
dP^A_t = \sigma^{P_A,b} dW_t + \sigma^{P_A,j} + O(dt),
\]
where \(\sigma^{P_A,b} = P^A \sigma_c; \quad \sigma^{P_A,j} = P^A_{t^+} - P^A_{t^-} \).

\[
dP_t = \sigma^{P,b} dW_t + \sigma^{P,j} + O(dt),
\]
where \(\sigma^{P,b} = P \sigma_c; \quad \sigma^{P,j} = P_{t^+} - P_{t^-} \).

\[
dP^{DI}_t = \sigma^{DI,b} dW_t + \sigma^{DI,j} + O(dt),
\]
where \(\sigma^{DI,b} = 0; \quad \sigma^{DI,j} = RF B_{t,t+T} - P^{DI}_t \),

where the sensitivity of disaster insurance with respect to the jump is derived from the fact that, immediately after the jump, the disaster insurance will surely pay 1$ at maturity, so its post-jump price is equal to that of a riskfree bond \(RF B_{t,t+T}\) of the same maturity.

From another perspective, the self-financing property of agent A’s portfolio \(\{\theta^A_{P,t}, \theta^A_{DI,t}, \theta^A_{RF B,t}\}\) (these are agent A’s positions in stock, disaster insurance and instantaneously risk-free bond respectively):

\[
dP^A = \theta^A_{P,t} dS_t + \theta^A_{DI,t} dP^{DI}_t + \theta^A_{RF B,t} dRF B_t + O(dt),
\]

\[
= \#dt + (\theta^A_{P,t} \theta^A_{DI,t}) \begin{pmatrix} \sigma^{P,b} & \sigma^{P,j} \\ \sigma^{DI,b} & \sigma^{DI,j} \end{pmatrix} \begin{pmatrix} dW_t \\ \Delta N_t \end{pmatrix}.
\]

By identifying the diffusion and jump parts of \(dP^A\) in (A.12), (A.13) we have

\[
(\theta^A_{P,t} \theta^A_{DI,t}) \begin{pmatrix} \sigma^{P,b} & \sigma^{P,j} \\ \sigma^{DI,b} & \sigma^{DI,j} \end{pmatrix} = (\sigma^{P_A,b} \sigma^{P_A,j}) \Rightarrow \begin{pmatrix} \theta^A_{P,t} \\ \theta^A_{DI,t} \end{pmatrix} = \begin{pmatrix} \sigma^{P,b} & \sigma^{DI,b} \\ \sigma^{P,j} & \sigma^{DI,j} \end{pmatrix}^{-1} \begin{pmatrix} \sigma^{P_A,b} \\ \sigma^{P_A,j} \end{pmatrix}.
\]

We need the “sensitivities” \(\sigma^{P,b}, \sigma^{DI,b}, \sigma^{P,j}, \sigma^{DI,j}, \sigma^{P_A,b}, \sigma^{P_A,j}\) in (A.12), (A.13), (A.14) to determine
the portfolio positions.

\[
\begin{pmatrix}
\theta_{t}^{A,P} \\
\theta_{t}^{A,DI}
\end{pmatrix} = \begin{pmatrix}
\sigma_{P,b} & 0 \\
\sigma_{P,b} & \sigma_{DI,j}
\end{pmatrix}^{-1} \begin{pmatrix}
\sigma_{P,A,b} \\
\sigma_{P,A,j}
\end{pmatrix} = \begin{pmatrix}
\frac{\sigma_{P,A,b}}{\sigma_{P,b}} \\
-\frac{\sigma_{P,j} \sigma_{P,A,b}}{\sigma_{P,b} \sigma_{DI,j}} + \frac{\sigma_{P,A,j}}{\sigma_{DI,j}}
\end{pmatrix}.
\]

And agent A’s position in money market account

\[
\theta_{t}^{A,RFB} = P_{t}^{A} - \theta_{t}^{A,P} P_{t} - \theta_{t}^{A,DI} P_{t}^{DI}.
\] (A.16)

We note in particular, from (A.12), (A.13) we have \(\sigma_{P,A,b} = P^{A} \sigma_{c} \), \(\sigma_{P,b} = P \sigma_{c} \), so agent A’s stock position is \(\theta_{t}^{A,P} = \frac{\sigma_{P,A,b}}{\sigma_{P,b}} = P_{t}^{A} \), or value fraction invested in stock of agent A is always one

\[
\frac{\theta_{t}^{A,P} P_{t}}{P_{t}^{A}} = 1.
\] (A.17)

Thus from (A.16), agent A’s position is riskless bond is \(\theta_{t}^{A,RFB} = -\theta_{t}^{A,DI} P_{t}^{DI} \). Finally, agent B’s portfolio positions can be found from market clearing condition: \(\theta_{t}^{B,P} = 1 - \theta_{t}^{A,P} \); \(\theta_{t}^{B,DI} = -\theta_{t}^{A,DI} \); \(\theta_{t}^{B,RFB} = -\theta_{t}^{A,RFB} \).

**B Boundedness of prices**

This appendix discusses the boundedness of securities prices in general heterogeneous-agent economy. As claimed in the main text, as long as agents have different but equivalent beliefs, necessary and sufficient condition for finite price of a security in heterogeneous-agent economy is that this price be finite under each agent’s beliefs in a single-agent economy. The proof proceeds as follows.

Suppose that the security pays dividend stream \(D_{t} \) (which can be either continuous or discrete in time). Let us denote \(S, S^{A}, S^{B} \) its prices in heterogeneous-agent, and single-agent economies.
respectively.

\[ S_t^A = E_t \left[ \int_0^\infty \frac{\tilde{z}_t^A}{\tilde{\zeta}_t^A} (C_{t+\tau}^A)^{1-\gamma^A} D_{t+\tau} d\tau \right], \]

\[ S_t^B = E_t \left[ \int_0^\infty \frac{\tilde{z}_t^B}{\tilde{\zeta}_t^B} (C_{t+\tau}^B)^{1-\gamma^B} D_{t+\tau} d\tau \right], \]

\[ S_t = E_t \left[ \int_0^\infty \frac{\tilde{z}_t^A}{\tilde{\zeta}_t^A} (C_{t+\tau}^A)^{1-\gamma^A} D_{t+\tau} d\tau \right] = E_t \left[ \int_0^\infty \frac{\tilde{z}_t^B}{\tilde{\zeta}_t^B} (C_{t+\tau}^B)^{1-\gamma^B} D_{t+\tau} d\tau \right], \]

where the last equality is a consequence of the FOC in heterogeneous-agent economy.

Necessary condition \( S < \infty \Rightarrow S^A, S^B < \infty \): This is immediate by noting that since individual consumptions are always non-negative \( 0 \leq C_{t+\tau}^A, C_{t+\tau}^B \leq C_{t+\tau} \forall \tau \), we have

\[ \tilde{z}_t^A (C_{t+\tau}^A)^{-\gamma^A} \geq \tilde{z}_t^A (C_{t+\tau}^A)^{-\gamma^A} \Rightarrow S_t \geq S_t^A \forall t, \]

and thus \( S_t^A \) is finite whenever \( S_t \) is finite. By identical reason, \( S_t^B \) is finite whenever \( S_t \) is finite.

Sufficient condition \( S^A, S^B < \infty \Rightarrow S < \infty \): This is straightforward by noting that, for any fixed number \( k \in (0, 1) \) (without loss of generality, we can e.g. fix \( k = 0.5 \) to visualize this):

\[ \frac{C^A}{C} < k \Leftrightarrow \frac{(C^A)^{1-\gamma^A}}{(C^{-\gamma^A})} > k^{-\gamma^A} \Rightarrow \frac{C^B}{C} > 1 - k \Leftrightarrow \frac{(C^B)^{1-\gamma^B}}{(C^{-\gamma^B})} < (1 - k)^{-\gamma^B}, \]

and vice versa. That is, at any moment \( t + \tau \), the integrand of price \( S \) is always bounded (up to a finite factor) by either the integrand of \( S^A \) or \( S^B \). Now as both \( S^A, S^B \) are finite, \( S \) is also finite.\(^{15}\)

This necessary and sufficient condition for bounded prices in heterogeneous-agent economy forms the rigorous basis to derive the explicit and adequate parameter restrictions \(^{16a}{16b}\) in single-agent. Let us consider the zero-coupon equity price in an economy with only agent i’s presence \( (i = 1, 2) \).

\[ \frac{1}{M_0} E_0^i [M_t C_t] \sim e^{-\rho t} E_0^i \left[ C_t^{1-\gamma_i} \right] = e^{-\rho t} E_0^i \left[ e^{(1-\gamma_i) c_t} \right] \]

\[ dc_t = \bar{g} dt + \sigma c dW_t + \Delta c_t. \]

\(^{15}\)The technical point that sum of possibly infinite numbers of same-direction inequalities remain an inequality of same direction is assured simply by the boundedness of both \( S^A, S^B \).
Concerning the affine jump part \((1 - \gamma^i) \Delta c_t \sim (1 - \gamma^i) d J_t\), the expectation is exponential affine, with coefficients satisfying Riccati ODEs

\[
E^0_t \left[ e^{(1-\gamma^i) J_t} \right] \sim e^{A_t + B_t \lambda^i_0}
\]

\[
\frac{dB_t}{dt} = -\kappa B_t + \frac{1}{2} \sigma_\lambda^2 B_t^2 + (\phi^P_i(1 - \gamma^i) - 1); \quad \frac{dA_t}{dt} = \kappa \lambda^i B_t; \quad A_0 = 0.
\]

For this expectation to be finite, it is necessary that \(B_t\) be bounded and thus \(\frac{dB_t}{dt}\) assume negative value at least in some parameter region. That is,

\[
\inf \frac{dB_t}{dt} = -\frac{1}{2} \kappa^2 + (\phi^P_i(1 - \gamma^i) - 1) < 0 \Rightarrow \kappa^2 > 2\sigma_\lambda^2 (\phi^P_i(1 - \gamma^i) - 1),
\]

(B.1)

for both \(i = 1, 2\). This is \((16a)\).

Asymptotically, \(B_t\) tends to its attracting fixed point \(B^*\) (at which point \(\frac{dB_t}{dt} = 0\) and \(\frac{dB_t}{dt}\) changes its sign from positive to negative as \(B_t\) increases from left to right of \(B^*\))

\[
B^* = \kappa - \sqrt{\kappa^2 - 2\sigma_\lambda^2 (\phi^P_i(1 - \gamma^i) - 1)} = \kappa - \sqrt{\frac{\kappa^2 + 2\sigma_\lambda^2 (1 - \phi^P_i(1 - \gamma^i))}{\sigma_\lambda^2}}.
\]

(B.2)

For equity price to be finite, the time integrand

\[
e^{-\rho t} E^0_0 \left[ C_t^{1-\gamma^i} \right] \sim e^{[-\rho + (1 - \gamma^i) \bar{g} + \frac{1}{2} \gamma^i - 1)^2 \sigma_c^2 + \kappa \lambda^i B^*] t},
\]

needs to be decreasing, or

\[
-\rho + (1 - \gamma^i) \bar{g} + \frac{1}{2} (\gamma^i - 1)^2 \sigma_c^2 + \kappa \lambda^i B^* < 0,
\]

(B.3)

for both \(i = 1, 2\). This is \((16b)\) after we plug in the above expression for \(B^*\).
